A *drug* is any biological substance, synthetic or non-synthetic, that is taken for non-dietary needs. It is usually synthesized outside of an organism, but introduced into an organism to produce its action. That is, when taken into the organisms body, it will produce some effects or alter some bodily functions (such as relieving symptoms, curing diseases or used as preventive medicine or any other purposes).

Note that natural endogenous biochemicals (such as hormones) can bind to the same receptor in the cell, producing the same effect as a drug. Thus, drug is merely an artificial definition that distinguishes whether that molecule is synthesized within an organism or outside an organism. For instance, insulin is a hormone that is synthesized in the body; it is considered as a hormone when it is synthesized by the pancreas inside the body, but if it is introduced into the body from outside, it is considered as a drug.

It is a substance which is not food, and which, when ingested, affects the functioning of the mind, or the body, or both. However, under the philosophy of Chinese medicine, food is also considered a drug as it affects particular parts of body and cures some diseases. Thus, food does satisfy the above definition of drug so long as ingestion of it would alter some bodily functions.

Contents

Health

Health is the functional and/or metabolic efficiency of an organism, at any moment in time, at both the cellular and global levels. All individual organisms, from the simplest to the most complex, vary between optimum health and zero health (dead).

In the medical field, health is commonly defined as an organism's ability to efficiently respond to challenges (stressors) and effectively restore and sustain a "state of balance," known as homeostasis.

Another widely accepted definition of health is that of the World Health Organization "WHO". It states that "health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity"[1]. In more recent years, this statement has been modified to include the ability to lead a "socially and economically productive life." The WHO definition is not without criticism, as some argue that health cannot be defined as a state at all, but must be seen as a process of continuous adjustment to the changing demands of living and of the changing meanings we give to life. The WHO definition is therefore considered by many as an idealistic goal rather than a realistic proposition.

The LaLonde report suggested that there are four general determinants of health which he called "human biology", "environment", "lifestyle", and "healthcare organization"[2] Thus, health is maintained through the science and practice of medicine, but can also be improved by individual effort. Physical fitness, weight loss, healthy eating, stress management training and stopping smoking and other substance abuse are examples of steps to improve one's health. Workplace programs are recognized by an increasingly large number of companies for their value in improving health and well-being of their employees, and increasing morale, loyalty and productivity at work. A company may provide a gym with exercise equipment, start smoking cessation programs, provide nutrition, weight or stress management training. Other programs may include health risk assessments, health screenings and body mass index monitoring.

An increasing measure of the health of populations is height, which is strongly regulated by nutrition and health care, among other standard of living and quality of life matters. The study of human growth, its regulators and its implications is known as auxology.

Wellness is a term sometimes used to describe the psychological state of being healthy, but is most often used in the field of alternative medicine to describe one's state of being.

Exercise

Physical exercise is the performance of some activity in order to develop or maintain physical fitness and overall health. It is often directed toward also honing athletic ability or skill. Frequent and regular physical exercise is an important component in the prevention of some of the diseases of affluence such as cancer, heart disease, cardiovascular disease, Type 2 diabetes and obesity.

Exercises are generally grouped into three types depending on the overall effect they have on the human body:

- Flexibility exercises such as stretching improve the range of motion of muscles and joints.
- Aerobic exercises such as walking and running focus on increasing cardiovascular endurance.
- Anaerobic exercises such as weight training or sprinting increase short-term muscle strength.

Physical exercise is considered important for maintaining physical fitness including healthy weight; building and maintaining healthy bones, muscles, and joints; promoting physiological well-being; reducing surgical risks; and strengthening the immune system.

Proper nutrition is at least as important to health as exercise. When exercising it becomes even more important to have good diet to ensure the body has the correct ratio of macronutrients whilst providing ample micronutrients, this is to aid the body with the recovery process following strenuous exercise. When the body falls short of proper nutrition, it gets into starvation mode developed through evolution and depends onto fat content for survival. Research suggest that the production of thyroid hormones can be negatively affected by repeated bouts of dieting and calorie restriction[3].

Proper rest and recovery is also as important to health as exercise, otherwise the body exists in a permanently injured state and will not improve or adapt adequately to the exercise.

The above two factors can be compromised by psychological compulsions (eating disorders such as exercise bulimia, anorexia, and other bulimias), misinformation, a lack of organization, or a lack of motivation. These all lead to a decreased state of health.

Delayed Onset Muscle Soreness can occur after any kind of exercise, particularly if the body is in an unconditioned state relative to that exercise.

Hygiene

Hygiene is the maintenance of healthy practices. In modern terminology, this is usually regarded as a particular reference to cleanliness. The term Hygiene originates as a reference to Hygieia, who was a daughter of Asclepius and the goddess of health, cleanliness and sanitation. The related term *personal grooming/grooming* means to enhance one's physical appearance or appeal for others, by removing obvious imperfections in one's appearance or improving one's hygiene.

Outward signs of good hygiene include the absence of visible dirt (including dust and stains on clothing) or of bad odor/smells. Since the development of the germ theory of disease, hygiene has come to mean any practice leading to the absence of harmful levels of bacteria.

Good hygiene is an aid to health, beauty, comfort, and social interactions. It directly aids in disease prevention and/or disease isolation. (That is, good hygiene will help keep one healthy and thus avoid illness. If one is ill, good hygiene can reduce one's contagiousness to others.)

Washing (with water) is the most common example of hygienic behavior. Washing is often done with soap or detergent which helps to remove oils and to break up dirt particles so they may be washed away.

Hygienic practices—such as frequent hand washing or the use of boiled (and thus sterilized) water in surgery/medical operations—have a profound impact on reducing the spread of disease. This is because they kill or remove disease-causing microbes (germs) in the immediate surroundings. For instance, washing one's hands after using the toilet and before handling food reduces the chance of spreading E. coli bacteria and Hepatitis A, both of which are spread from fecal contamination of food.

Adequate hygiene requires an adequate and convenient supply of clean water. In much of the developing world maintaining an acceptable level of cleanliness is difficult or impossible for much of the population due to lack of adequate water supply and sanitation. This results in the rapid spread and extent of diseases such as trachoma which are rare in the developed world.

Nutrition

Nutrition is a science which studies the relationship between diet and states of health and disease. Dieticians are Health professionals who are specialized in this area of expertise. They are also the only highly trained health professionals able to provide safe, evidence-based and accurate dietary advice and interventions.

Between the extremes of optimal health and death from starvation or malnutrition, there is an array of disease states that can be caused or alleviated by changes in diet. Deficiencies, excesses and imbalances in diet can produce negative impacts on health, which may lead to diseases such as scurvy, obesity or osteoporosis, as well as psychological and behavioral problems. Moreover, excessive ingestion of elements that have no apparent role in health, (e.g. lead, mercury, PCBs, dioxins), may incur toxic and potentially lethal effects, depending on the dose. The science of nutrition attempts to understand how and why specific dietary aspects influence health.

Mental health

Mental health is a concept refers to a human individual's emotional and psychological well-being. Merriam-Webster defines mental health as "A state of emotional and psychological well-being in which an individual is able to use his or her cognitive and emotional capabilities, function in society, and meet the ordinary demands of everyday life."

According to the World Health Organization (WHO), there is no one "official" definition of mental health. Cultural differences, subjective assessments, and competing professional theories all affect how "mental health" is defined. In general, most experts agree that "mental health" and "mental illness" are not opposites. In other words, the absence of a recognized mental disorder is not necessarily an indicator of mental health.

One way to think about mental health is by looking at how effectively and successfully a person functions. Feeling capable and competent; being able to handle normal levels of stress, maintain satisfying relationships, and lead an independent life; and being able to "bounce back," or recover from difficult situations, are all signs of mental health.

Health science

Health science is the discipline of applied science which deals with human and animal health. There are two parts to health science: the study, research, and knowledge of health and the application of that knowledge to improve health, cure diseases, and understanding how humans and animals function. Research builds primarily on the pure sciences of biology, chemistry, and physics as well as social sciences (for example medical sociology). Other fields which made an exceptionally significant contribution to the health sciences include biochemistry, biotechnology, engineering, epidemiology, genetics, nursing, pharmacology, pharmacy, public health, and medicine. The health sciences industry, a multi-billion dollar business, is a subset of the life sciences, medical care, and diagnosis industries.

Historical overview

The foundations for the health science fields are as old as the human race. Humans have always been in need of solutions to address illness, injury, and various health related issues such as childbirth. With modern technology and the backing of the pure sciences, the scientific accuracy of these fields has greatly improved. Nevertheless, many cultures have used and continue to use various herbs and other culturally specific solutions to help solve health problems that may or may not be backed by any scientific support.

Application of health-related knowledge

Health deliveries

There are a large number of health professions. The terms medicine or biomedicine, and medical doctor or M.D. refer to dominant conventional practices in the West.

There are a wide range of traditional areas of health science. The most common areas are: medicine, nursing, midwifery, and various forms of therapy to supplement the healing process and restore proper activity (e.g. Dietetics, recreational, physical, occupational, speech, and respiratory). Health science includes both the study and application of preventing and curing human diseases and disorders. Medical doctors include physicians and surgeons. There are many different branches of medicine; the other health care professions also have specialties or focus on specific populations or settings of care. Public health studies the effect of environmental factors such as available health care resources on the health of the general population, often focusing on particular populations, such as mothers and children. Dietitians educate people about proper nutrition, particularly specific dietary needs of populations such as people with diabetes, breastfeeding women, and people with celiac disease. Other less common medical areas include first aid and triage.

Dental health has grown in importance in recent decades making dentistry a major field of health sciences. Counselling, hospice care, home care, nutrition, medical social work, alternative medicine, pharmacology, and toxicology are all considered part of health science.

Veterinary medicine is the health science dedicated exclusively to the care of animals. Veterinary medicine is involved in preventing and curing animal diseases and disorders, inspecting animal originated food (like milk and meat) and animal husbandry.

Contemporary themes

Because health science deals with human life, issues of medical ethics, an important area of ethics, arise frequently. Medical ethics includes questions on topics such as a patient's right to privacy. Euthanasia, abortion, human cloning, stem cell research and genetic engineering are especially controversial issues directly related to health science.

Medicine

Medicine is the branch of health science and the sector of public life concerned with maintaining or restoring human health through the study, diagnosis, treatment and possible prevention of disease and injury. It is both an area of knowledge – a science of body systems, their diseases and treatment – and the applied practice of that knowledge.

Overview

Western medical care is shared between medical professionals (physicians) and other professionals such as physician assistants, nurses and pharmacists, sometimes known as allied health professionals. Historically, only those with a medical doctorate have been considered to practice medicine. Clinicians (licensed professionals who deal with patients) can be physicians, nurses, therapists or others. The medical profession is the social and occupational structure of the group of people formally trained and authorized to apply medical knowledge. Many countries and legal jurisdictions have legal limitations on who may practice medicine.

Medicine comprises various specialized sub-branches, such as cardiology, pulmonology, neurology, or other fields such as sports medicine, research or public health.

Human societies have had various different systems of health care practice since at least the beginning of recorded history. Medicine, in the modern period, is the mainstream scientific tradition which developed in the Western world since the early Renaissance (around 1450). Many other traditions of health care are still practiced throughout the world; most of these are separate from Western medicine, which is also called *biomedicine*, *allopathic medicine* or the Hippocratic tradition. The most highly developed of these are traditional Chinese medicine, Tibetan medicine and the Ayurvedic traditions of India and Sri Lanka. Various non-mainstream traditions of health care have also developed in the Western world. These systems are sometimes considered companions to Hippocratic medicine, and sometimes are seen as competition to the Western tradition. Few of them have any scientific confirmation of their tenets, because if they did they would be brought into the fold of Western medicine.

"Medicine" is also often used amongst medical professionals as shorthand for internal medicine. Veterinary medicine is the practice of health care in animal species other than human beings.

History of medicine

The earliest type of medicine in most cultures was the use of plants (Herbalism) and animal parts. This was usually in concert with 'magic' of various kinds in which: animism (the notion of inanimate objects having spirits); spiritualism (here meaning an appeal to gods or communion with ancestor spirits); shamanism (the vesting of an individual with mystic powers); and divination (the supposed obtaining of truth by magic means), played a major role.

The practice of medicine developed gradually, and separately, in ancient Egypt, India, China, Greece, Persia and elsewhere. Medicine as it is practiced now developed largely in the late eighteenth century and early nineteenth century in England (William Harvey, seventeenth century), Germany (Rudolf Virchow) and France (Jean-Martin Charcot, Claude Bernard and others). The new, "scientific" medicine (where results are testable and repeatable) replaced early Western traditions of medicine, based on herbalism, the Greek "four humours" and other pre-modern theories.[citation needed] The focal points of development of clinical medicine shifted to the United Kingdom and the USA by the early

1900s (Canadian-born)Sir William Osler, Harvey Cushing). Possibly the major shift in medical thinking was the gradual rejection in the 1400's of what may be called the 'traditional authority' approach to science and medicine. This was the notion that because some prominent person in the past said something must be so, then that was the way it was, and anything one observed to the contrary was an anomaly (which was paralleled by a similar shift in European society in general - see Copernicus's rejection of Ptolemy's theories on astronomy). People like Vesalius led the way in improving upon or indeed rejecting the theories of great authorities from the past such as Galen, Hippocrates, and Avicenna/Ibn Sina, all of whose theories were in time almost totally discredited. Such new attitudes were also only made possible by the weakening of the Roman Catholic church's power in society, especially in the Republic of Venice.

Evidence-based medicine is a recent movement to establish the most effective algorithms of practice (ways of doing things) through the use of the scientific method and modern global information science by collating all the evidence and developing standard protocols which are then disseminated to healthcare providers. One problem with this 'best practice' approach is that it could be seen to stifle novel approaches to treatment.

Genomics and knowledge of human genetics is already having some influence on medicine, as the causative genes of most monogenic genetic disorders have now been identified, and the development of techniques in molecular biology and genetics are influencing medical practice and decision-making.

Pharmacology has developed from herbalism and many drugs are still derived from plants (atropine, ephedrine, warfarin, aspirin, digoxin, vinca alkaloids, taxol, hyoscine, etc). The modern era really began with Koch's discoveries around 1880 of the transmission of disease by bacteria, and then the discovery of antibiotics shortly thereafter around 1900. The first major class of antibiotics was the sulfa drugs, derived originally from azo dyes. Throughout the twentieth century, major advances in the treatment of infectious diseases were observable in (Western) societies. The medical establishment is now developing drugs that are targeted towards one particular disease process. Thus drugs are being developed to minimise the side effects of prescribed drugs, to treat cancer, geriatric problems, long-term problems (such as high cholesterol), chronic diseases (type 2 diabetes), lifestyle and degenerative diseases such as (arthritis) and Alzheimer's disease.

Practice of medicine

The practice of medicine combines both science as the evidence base and art in the application of this medical knowledge in combination with intuition and clinical judgement to determine the treatment plan for each patient.

Central to medicine is the patient-physician relationship established when a person with a health concern seeks a physician's help; the 'medical encounter'. Other health professionals similarly establish a relationship with a patient and may perform various interventions, e.g. nurses, radiographers and therapists.

As part of the medical encounter, the healthcare provider needs to:

- develop a relationship with the patient

- gather data (medical history, systems enquiry, and physical examination, combined with laboratory or imaging studies (investigations))
- analyze and synthesize that data (assessment and/or differential diagnoses), and then:
- develop a treatment plan (further testing, therapy, watchful observation, referral and follow-up)
- treat the patient accordingly
- assess the progress of treatment and alter the plan as necessary (management).

The medical encounter is documented in a medical record, which is a legal document in many jurisdictions.[1]

Health care delivery systems

Medicine is practiced within the medical system, which is a legal, credentialing and financing framework, established by a particular culture or government. The characteristics of a health care system have significant effect on the way medical care is delivered.

Financing has a great influence as it defines who pays the costs. Aside from tribal cultures, the most significant divide in developed countries is between universal health care and market-based health care (such as practiced in the U.S.). Universal health care might allow or ban a parallel private market. The latter is described as single-payor system.

Transparency of information is another factor defining a delivery system. Access to information on conditions, treatments, quality and pricing greatly affects the choice by patients / consumers and therefore the incentives of medical professionals. While US health care system has come under fire for lack of openness, new legislation may encourage greater openness. There is a perceived tension between the need for transparency on the one hand and such issues as patient confidentiality and the possible exploitation of information for commercial gain on the other.

Health care delivery

Medical care delivery is classified into primary, secondary and tertiary care.

Primary care medical services are provided by physicians or other health professionals who has first contact with a patient seeking medical treatment or care. These occur in physician's office, clinics, nursing homes, schools, home visits and other places close to patients. About 90% of medical visits can be treated by the primary care provider. These include treatment of acute and chronic illnesses, preventive care and health education for all ages and both sexes.

Secondary care medical services are provided by medical specialists in their offices or clinics or at local community hospitals for a patient referred by a primary care provider who first diagnosed or treated the patient. Referrals are made for those patients who required the expertise or procedures performed by specialists. These include both ambulatory care and inpatient services, emergency rooms, intensive care medicine, surgery services, physical therapy, labor and delivery, endoscopy units, diagnostic laboratory and medical imaging

services, hospice centers, etc. Some primary care providers may also take care of hospitalized patients and deliver babies in a secondary care setting.

Tertiary care medical services are provided by specialist hospitals or regional centers equipped with diagnostic and treatment facilities not generally available at local hospitals. These include trauma centers, burn treatment centers, advanced neonatology unit services, organ transplants, high-risk pregnancy, radiation oncology, etc.

Modern medical care also depends on information - still delivered in many health care settings on paper records, but increasingly nowadays by electronic means.

Physician-patient relationship

The physician-patient relationship and interaction is a central process in the practice of medicine. There are many perspectives from which to understand and describe it.

An idealized physician's perspective, such as is taught in medical school, sees the core aspects of the process as the physician learning the patient's symptoms, concerns and values; in response the physician examines the patient, interprets the symptoms, and formulates a diagnosis to explain the symptoms and their cause to the patient and to propose a treatment. The job of a physician is similar to a human biologist: that is, to know the human frame and situation in terms of normality. Once the physician knows what is normal and can measure the patient against those norms, he or she can then determine the particular departure from the normal and the degree of departure. This is called the diagnosis.

The four great cornerstones of diagnostic medicine are anatomy (structure: what is there), physiology (how the structure/s work), pathology (what goes wrong with the anatomy and physiology) and psychology (mind and behaviour). In addition, the physician should consider the patient in their 'well' context rather than simply as a walking medical condition. This means the socio-political context of the patient (family, work, stress, beliefs) should be assessed as it often offers vital clues to the patient's condition and further management. In more detail, the patient presents a set of complaints (the symptoms) to the physician, who then obtains further information about the patient's symptoms, previous state of health, living conditions, and so forth. The physician then makes a review of systems (ROS) or systems enquiry, which is a set of ordered questions about each major body system in order: general (such as weight loss), endocrine, cardio-respiratory, etc. Next comes the actual physical examination; the findings are recorded, leading to a list of possible diagnoses. These will be in order of probability. The next task is to enlist the patient's agreement to a management plan, which will include treatment as well as plans for follow-up. Importantly, during this process the healthcare provider educates the patient about the causes, progression, outcomes, and possible treatments of his ailments, as well as often providing advice for maintaining health. This teaching relationship is the basis of calling the physician doctor, which originally meant "teacher" in Latin. The patient-physician relationship is additionally complicated by the patient's suffering (patient derives from the Latin patior, "suffer") and limited ability to relieve it on his/her own. The physician's expertise comes from his knowledge of what is healthy and normal contrasted with knowledge and experience of other people who have suffered similar symptoms (unhealthy and abnormal), and the proven ability to relieve it with medicines (pharmacology) or other therapies about

which the patient may initially have little knowledge, although the latter may be better performed by a pharmacist.

The physician-patient relationship can be analyzed from the perspective of ethical concerns, in terms of how well the goals of non-maleficence, beneficence, autonomy, and justice are achieved. Many other values and ethical issues can be added to these. In different societies, periods, and cultures, different values may be assigned different priorities. For example, in the last 30 years medical care in the Western World has increasingly emphasized patient autonomy in decision making.

The relationship and process can also be analyzed in terms of social power relationships (e.g., by Michel Foucault), or economic transactions. Physicians have been accorded gradually higher status and respect over the last century, and they have been entrusted with control of access to prescription medicines as a public health measure. This represents a concentration of power and carries both advantages and disadvantages to particular kinds of patients with particular kinds of conditions. A further twist has occurred in the last 25 years as costs of medical care have risen, and a third party (an insurance company or government agency) now often insists upon a share of decision-making power for a variety of reasons, reducing freedom of choice of healthcare providers and patients in many ways.

The quality of the patient-physician relationship is important to both parties. The better the relationship in terms of mutual respect, knowledge, trust, shared values and perspectives about disease and life, and time available, the better will be the amount and quality of information about the patient's disease transferred in both directions, enhancing accuracy of diagnosis and increasing the patient's knowledge about the disease. Where such a relationship is poor the physician's ability to make a full assessment is compromised and the patient is more likely to distrust the diagnosis and proposed treatment. In these circumstances and also in cases where there is genuine divergence of medical opinions, a second opinion from another physician may be sought.

In some settings, e.g. the hospital ward, the patient-physician relationship is much more complex, and many other people are involved when somebody is ill: relatives, neighbors, rescue specialists, nurses, technical personnel, social workers and others.

Clinical skills

A complete medical evaluation includes a medical history, a systems enquiry, a physical examination, appropriate laboratory or imaging studies, analysis of data and medical decision making to obtain diagnoses, and a treatment plan.[2]

The components of the medical history are:

- Chief complaint (CC): the reason for the current medical visit. These are the 'symptoms.' They are in the patient's own words and are recorded along with the duration of each one. Also called 'presenting complaint.'
- History of present illness / complaint (HPI): the chronological order of events of symptoms and further clarification of each symptom.
- Current activity: occupation, hobbies, what the patient actually does.

- Medications: what drugs the patient takes including over-the-counter, and home remedies, as well as herbal medicines/herbal remedies such as St. John's Wort. Allergies are recorded.
- Past medical history (PMH/PMHx): concurrent medical problems, past hospitalizations and operations, injuries, past infectious diseases and/or vaccinations, history of known allergies.
- Social history (SH): birthplace, residences, marital history, social and economic status, habits (including diet, medications, tobacco, alcohol).
- Family history (FH): listing of diseases in the family that may impact the patient. A family tree is sometimes used.
- Review of systems (ROS) or systems enquiry: an set of additional questions to ask which may be missed on HPI, generally following the body's main organ systems (heart, lungs, digestive tract, urinary tract, etc).

The physical examination is the examination of the patient looking for signs of disease ('Symptoms' are what the patient volunteers, 'signs' are what the healthcare provider detects by examination). The healthcare provider uses the senses of sight, hearing, touch, and sometimes smell (taste has been made redundant by the availability of modern lab tests). Four chief methods are used: inspection, palpation (feel), percussion (tap to determine resonance characteristics), and auscultation (listen); smelling may be useful (e.g. infection, uremia, diabetic ketoacidosis). The clinical examination involves study of:

- Vital signs including height, weight, body temperature, blood pressure, pulse, respiration rate, hemoglobin oxygen saturation
- General appearance of the patient and specific indicators of disease (nutritional status, presence of jaundice, pallor or clubbing)
- Skin
- Head, eye, ear, nose, and throat (HEENT)
- Cardiovascular (heart and blood vessels)
- Respiratory (large airways and lungs)
- Abdomen and rectum
- Genitalia (and pregnancy if the patient is or could be pregnant)
- Musculoskeletal (spine and extremities)
- Neurological (consciousness, awareness, brain, cranial nerves, spinal cord and peripheral nerves)
- Psychiatric (orientation, mental state, evidence of abnormal perception or thought)

Laboratory and imaging studies results may be obtained, if necessary.

The medical decision-making (MDM) process involves analysis and synthesis of all the above data to come up with a list of possible diagnoses (the differential diagnoses), along with an idea of what needs to be done to obtain a definitive diagnosis that would explain the patient's problem.

The treatment plan may include ordering additional laboratory tests and studies, starting therapy, referral to a specialist, or watchful observation. Follow-up may be advised.

This process is used by primary care providers as well as specialists. It may take only a few minutes if the problem is simple and straightforward. On the other hand, it may take

weeks in a patient who has been hospitalized with bizarre symptoms or multi-system problems, with involvement by several specialists.

On subsequent visits, the process may be repeated in an abbreviated manner to obtain any new history, symptoms, physical findings, and lab or imaging results or specialist consultations.

Branches of medicine

Working together as an interdisciplinary team, many highly trained health professionals besides medical practitioners are involved in the delivery of modern health care. Some examples include: nurses, laboratory scientists, pharmacists, physiotherapists, respiratory therapists, speech therapists, occupational therapists, dietitians and bioengineers.

The scope and sciences underpinning human medicine overlap many other fields. Dentistry and psychology, while separate disciplines from medicine, are considered medical fields.

Midlevel Practitioner

Physician assistants, nurse practitioners and midwives treat patients and prescribe medication in many legal jurisdictions.

Veterinary Medicine

Veterinarians applies similar techniques as physicians to the care of animals.

Physicians have many specializations and subspecializations which are listed below. There are variations from country to country regarding which specialities certain subspecialities are in.

Diagnostic specialties

- Clinical laboratory sciences are the clinical diagnostic services which apply laboratory techniques to diagnosis and management of patients. In the United States these services are supervised by a pathologist. The personnel that work in these medical laboratory departments are technically trained staff, each of whom usually hold a medical technology degree, who actually perform the tests, assays, and procedures needed for providing the specific services.
- Pathology is the branch of medicine that deals with the study of diseases and the morphologic, physiologic changes produced by them. As a diagnostic specialty, pathology can be considered the basis of modern scientific medical knowledge and plays a large rôle in evidence-based medicine. Many modern molecular tests such as flow cytometry, polymerase chain reaction (PCR), immunohistochemistry, cytogenetics, gene rearragements studies and fluorescent in situ hybridization (FISH) fall within the territory of pathology.

- Radiology is concerned with imaging of the human body, e.g. by x-rays, x-ray computed tomography, ultrasonography, and nuclear magnetic resonance tomography.

Clinical disciplines

- Anesthesiology (AE) or anaesthesia (BE) is the clinical discipline concerned with providing anesthesia. Pain medicine is often practiced by specialised anesthesiologists.
- Dermatology is concerned with the skin and its diseases. In the UK, dermatology is a subspeciality of general medicine.
- Emergency medicine is concerned with the diagnosis and treatment of acute or life-threatening conditions, including trauma, surgical, medical, pediatric, and psychiatric emergencies.
- General practice, family practice, family medicine or primary care is, in many countries, the first port-of-call for patients with non-emergency medical problems. Family practitioners are usually able to treat over 90% of all complaints without referring to specialists.
- Hospital medicine is the general medical care of hospitalized patients. Physicians whose primary professional focus is hospital medicine are called hospitalists in the USA.
- Internal medicine is concerned with systemic diseases of adults, i.e. those diseases that affect the body as a whole (restrictive, current meaning), or with all adult non-operative somatic medicine (traditional, inclusive meaning), thus excluding pediatrics, surgery, gynecology and obstetrics, and psychiatry. There are several subdisciplines of internal medicine:
    - Cardiology
    - Endocrinology
    - Gastroenterology
    - Hematology
    - Infectious Diseases
    - Intensive care medicine
    - Nephrology
    - Oncology
    - Pulmonology
    - Rheumatology
- Neurology is concerned with the diagnosis and treatment of nervous system diseases. It is a subspeciality of general medicine in the UK.
- Obstetrics and gynecology (often abbreviated as Ob/Gyn) are concerned respectively with childbirth and the female reproductive and associated organs. Reproductive medicine and fertility medicine are generally practiced by gynecological specialists.

- Palliative care is a relatively modern branch of clinical medicine that deals with pain and symptom relief and emotional support in patients with terminal illnesses including cancer and heart failure.
- Pediatrics (AE) or paediatrics (BE) is devoted to the care of infants, children, and adolescents. Like internal medicine, there are many pediatric subspecialities for specific age ranges, organ systems, disease classes, and sites of care delivery. Most subspecialities of adult medicine have a pediatric equivalent such as pediatric cardiology, pediatric endocrinology, pediatric gastroenterology, pediatric hematology, pediatric oncology, pediatric ophthalmology, and neonatology.
- Physical medicine and rehabilitation (or physiatry) is concerned with functional improvement after injury, illness, or congenital disorders.
- Preventive medicine is the branch of medicine concerned with preventing disease.
- Psychiatry is the branch of medicine concerned with the bio-psycho-social study of the etiology, diagnosis, treatment and prevention of cognitive, perceptual, emotional and behavioral disorders. Related non-medical fields include psychotherapy and clinical psychology.
- Radiation therapy is concerned with the therapeutic use of ionizing radiation and high energy elementary particle beams in patient treatment.
- Radiology is concerned with the interpretation of imaging modalities including x-rays, ultrasound, radioisotopes, and MRI (Magnetic Resonance Imaging). A newer branch of radiology, interventional radiology, is concerned with using medical devices to access areas of the body with minimally invasive techniques.
- Surgical specialties employ operative treatment. These include Orthopedics, Urology, Ophthalmology, Neurosurgery, Plastic Surgery, Otolaryngology and various subspecialties such as transplant and cardiothoracic. Some disciplines are highly specialized and are often not considered subdisciplines of surgery, although their naming might suggest so.
- Urgent care focuses on delivery of unscheduled, walk-in care outside of the hospital emergency department for injuries and illnesses that are not severe enough to require care in an emergency department.
- Gender-based medicine studies the biological and physiological differences between the human sexes and how that affects differences in disease.

Interdisciplinary fields

Interdisciplinary sub-specialties of medicine are:

- Aerospace medicine deals with medical problems related to flying and space travel.
- Bioethics is a field of study which concerns the relationship between biology, science, medicine and ethics, philosophy and theology.

- Biomedical Engineering is a field dealing with the application of engineering principles to medical practice.
- Clinical pharmacology is concerned with how systems of therapeutics interact with patients.
- Conservation medicine studies the relationship between human and animal health, and environmental conditions. Also known as ecological medicine, environmental medicine, or medical geology.
- Diving medicine (or hyperbaric medicine) is the prevention and treatment of diving-related problems.
- Evolutionary medicine is a perspective on medicine derived through applying evolutionary theory.
- Forensic medicine deals with medical questions in legal context, such as determination of the time and cause of death.
- Medical humanities includes the humanities (literature, philosophy, ethics, history and religion), social science (anthropology, cultural studies, psychology, sociology), and the arts (literature, theater, film, and visual arts) and their application to medical education and practice.
- eHealth, Medical informatics, and medical computer science are relatively recent fields that deal with the application of computers and information technology to medicine.
- Nosology is the classification of diseases for various purposes.
- Pharmacogenomics is a form of individualized medicine.
- PanVascular Medicine is an approach to deal with the problems of highly specialised but both, medical and economical inefficiently arranged human resources and medical equipment in today's vascular care facilities
- Sports medicine deals with the treatment and preventive care of athletics, amateur and professional. The team includes specialty physicians and surgeons, athletic trainers, physical therapists, coaches, other personnel, and, of course, the athlete.
- Therapeutics is the field, more commonly referenced in earlier periods of history, of the various remedies that can be used to treat disease and promote health
- Travel medicine or emporiatrics deals with health problems of international travelers or travelers across highly different environments.

Medical education

Medical education is education related to the practice of being a medical practitioner, either the initial training to become a physician or further training thereafter.

Medical education and training varies considerably across the world, however typically involves entry level education at a university medical school, followed by a period of supervised practice (Internship and/or Residency) and possibly postgraduate vocational training. Continuing medical education is a requirement of many regulatory authorities.

Various teaching methodologies have been utilised in medical education, which is an active area of educational research.

Legal restrictions

In most countries, it is a legal requirement for medical doctors to be licensed or registered. In general, this entails a medical degree from a university and accreditation by a medical board or an equivalent national organization, which may ask the applicant to pass exams. This restricts the considerable legal authority of the medical profession to physicians that are trained and qualified by national standards. It is also intended as an assurance to patients and as a safeguard against charlatans that practice inadequate medicine for personal gain. While the laws generally require medical doctors to be trained in "evidence based", Western, or Hippocratic Medicine, they are not intended to discourage different paradigms of health and healing, such as alternative medicine or faith healing.

Criticism

Criticism of medicine has a long history. In the Middle Ages, some people did not consider it a profession suitable for Christians, as disease was often considered God sent. God was considered to be the 'divine physician' who sent illness or healing depending on his will. However many monastic orders, particularly the Benedictines, considered the care of the sick as their chief work of mercy. Barber-surgeons (they had the sharpest knives) generally had a bad reputation that was not to improve until the development of academic surgery as a speciality of medicine, rather than an accessory field.

Through the course of the twentieth century, healthcare providers focused increasingly on the technology that was enabling them to make dramatic improvements in patients' health. The ensuing development of a more mechanistic, detached practice, with the perception of an attendant loss of patient-focused care, known as the medical model of health, led to further criticisms. This issue started to reach collective professional consciousness in the 1970s and the profession had begun to respond by the 1980s and 1990s.

Perhaps the most devastating criticism of modern medicine came from Ivan Illich. In his 1976 work Medical Nemesis, Illich stated that modern medicine only medicalises disease and causes loss of health and wellness, while generally failing to restore health by eliminating disease. This medicalisation of disease forces the human to become a lifelong patient.[3]Other less radical philosophers have voiced similar views, but none were as virulent as Illich. Another example can be found in Technopoly: The Surrender of Culture to Technology by Neil Postman, 1992, which criticises overreliance on technological means in medicine.

Criticism of modern medicine has led to some improvements in the curricula of medical schools, which now teach students systematically on medical ethics, holistic approaches to medicine, the biopsychosocial model and similar concepts.

The inability of modern medicine to properly address many common complaints continues to prompt many people to seek support from alternative medicine. Although most alternative approaches lack scientific validation, some may be effective in individual cases. The bioscience and alternative health care paradigms may differ to such an extent that what constitutes scientific evidence is contested. Many physicians practice alternative medicine

alongside "orthodox" approaches but the general body of medical practitioners is often criticised for ignoring the purported value of alternative medicine.

Medical errors are also the focus of many complaints and negative coverage. Practitioners of human factors engineering believe that there is much that medicine may usefully gain by emulating concepts in aviation safety, where it was long ago realized that it is dangerous to place too much responsibility on one "superhuman" individual and expect him or her not to make errors. Reporting systems and checking mechanisms are becoming more common in identifying sources of error and improving practice.

Radical critics of certain medical traditions may hold that whole fields or traditions of medicine are intrinsically harmful or ineffective. They would reject any use or support of practices belonging to that tradition. However, generally, there is a spectrum of efficacy on which all traditions lie; some are more effective, some are less effective, but nearly all contain some harmful practices and some effective ones. Naturally, though, most individuals or groups seeking a health care practice to improve their own health would seek a tradition with the maximum degree of efficacy. There is no doubt whatsoever that Western Allopathic medicine, together with its cohorts of improved hygiene and nutrition, have been collectively responsible for most of the improvements in health worldwide over the last century or so, including: increasing longevity, decreased child mortality, increasing population numbers, better ability to monitor and halt disease spread and outbreaks, improved access to health care for all strata of society.

Drugs

A *drug* is any biological substance, synthetic or non-synthetic, that is taken for non-dietary needs. It is usually synthesized outside of an organism, but introduced into an organism to produce its action. That is, when taken into the organisms body, it will produce some effects or alter some bodily functions (such as relieving symptoms, curing diseases or used as preventive medicine or any other purposes).

Note that natural endogenous biochemicals (such as hormones) can bind to the same receptor in the cell, producing the same effect as a drug. Thus, drug is merely an artificial definition that distinguishes whether that molecule is synthesized within an organism or outside an organism. For instance, insulin is a hormone that is synthesized in the body; it is considered as a hormone when it is synthesized by the pancreas inside the body, but if it is introduced into the body from outside, it is considered as a drug.

It is a substance which is not food,[1] and which, when ingested, affects the functioning of the mind, or the body, or both. However, under the philosophy of Chinese medicine, food is also considered a drug as it affects particular parts of body and cures some diseases. Thus, food does satisfy the above definition of drug so long as ingestion of it would alter some bodily functions.

Drugs used as medicines

Main article: Medication

A medication is a drug taken to cure or reduce symptoms of an illness or medical condition, or may use as preventive medicine that has future benefits but does not treat any existing or pre-existing diseases or symptoms. Dispensing of medication is often regulated by the government into three categories -- over the counter (OTC) medications, which are available in pharmacies and and supermarket's without special restrictions, behind the counter (BTC), which are dispensed by a pharmacist without needing a doctor's prescription, and Prescription only medicines (POM), which must be prescribed by a licensed medical professional, usually a physician.

Most OTC medications are generally considered to be safe enough that most people will not hurt themselves if they are taken as instructed. In UK, BTC medicine is called pharmacy medicines which can only be sold in registered pharmacies, by or under the supervision of a pharmacist. However, the precise distinction between OTC and prescription depends on the legal jurisdiction.

Medications are typically produced by pharmaceutical companies and are often patented to protect their exclusive rights to produce them, but they can also be derived from naturally occurring substance in plants called herbal medicine. Those that are not patented (or with expired patents) are called generic drugs since they can be produced by other companies without restrictions or licenses from the patent holder.

Recreational drugs

Recreational drug use is the use of psychoactive drugs for recreational purposes rather than for work, medical or spiritual purposes. Much controversy has arisen over recreational drug use, and governments across the world have regulated the consumption and/or distribution of drugs in the name of fighting drug abuse, but many countries' laws are criticised for being passed under ulterior motives or for being hypocritical.

List of drugs

See list of drugs for an alphabetical list of drugs by name. Many drugs have more than one name and, therefore, the same drug may be listed more than once. Brand names and generic names are differentiated by the use of capital initials for the former.

Footnotes

1. ^ Some substances, such as beers, wines, and some fungi, are sometimes regarded as both foods and drugs

Drug diversion

In the terminology of the Drug Enforcement Administration, *diversion* is the use of prescription drugs for recreational purposes. The term comes from the "diverting" of the drugs from their original purposes.

note: Drug Diversion may also refer to programs available to first time drug law infractors which "divert" them from the criminal system to a program of education and rehabilitation.

Drugs that are diverted, in an approximate order of popularity

- Opioids (opium analogues) such as hydrocodone and OxyContin. These have similar effects to opium and heroin.
- Pseudoephedrine-containing drugs sold over the counter are used as an ingredient to make methamphetamine.

- DXM, the active ingredient of Robitussin, is abused for its effects which are similar to Ketamine and PCP.
- Depressants such as Valium.
- Antidepressants, which are often essentially stimulants, and are often snorted by abusers.

The DEA is doing some work to try and stop drug diversion. For example, sales of Pseudoephedrine are limited in certain stores.

Some critics feel that the importance of drug diversion is glossed over in the media and popular discussion. For example, in the recent case of Rush Limbaugh being accused of abusing pain-killers, it was felt by some that the similarity between the pain killers and heroin was not made clear. The higher dose pills of prescription pain killers are often stronger than the street rock heroin sold in most cities, and are preferred or at least used indiscriminately by opiate drug abusers.

Some critics contend however that drug diversion has been purposely allowed to happen, primarily by opioid manufacturers who profit off of the addiction of their customers. They also point to new products such as "dex-alone" which is a pill marketed specifically that it contains pure DXM without other compounds which would have an adverse effect at the levels of abuse.

Registration of drug suppliers

21 U.S.C. § 822 of the Controlled Substances Act provides for registration of manufacturers and distributors of Scheduled substances. The criteria for registering manufacturers of Schedule I and II drugs are particularly strict and call for "limiting the importation and bulk manufacture of such controlled substances to a number of establishments which can produce an adequate and uninterrupted supply of these substances under adequately competitive conditions for legitimate medical, scientific, research, and industrial purposes". The Attorney General must make a positive determination that the registration would be "consistent with the public interest".

For manufacturers of other drugs, and for drug distributors, the regulations are substantially less strict: "The Attorney General shall register an applicant . . . unless he determines that the issuance of such registration is inconsistent with the public interest". The criteria for both manufacture and distribution is somewhat biased in favor of established industries, favoring "past experience" and a record of compliance with drug laws[1].

Drug overdose

A *drug overdose* occurs when a drug is ingested in quantities and/or concentrations large enough to overwhelm the homeostasis of a living organism, causing severe illness or death. It is a type of poisoning.

Types

The word "overdose" implies that there is a safe dosage and therefore the term overdose is commonly only applied to drugs, not poisons.

Drug overdoses are sometimes caused intentionally to commit suicide, but many drug overdoses are accidental and are usually the result of either irresponsible behavior (such as overindulging at a party), or the misreading of product labels. Other causes of overdose (especially heroin) include multiple drug use with counter indications (cocaine/amphetamines/alcohol) or use after a period of abstinence.

A common unintentional overdose in young children involves multi-vitamins containing iron. Iron is a component of the hemoglobin molecule in blood, used to transport oxygen to living cells. When taken in small amounts, iron allows the body to replenish hemoglobin, but in large amounts it causes severe pH imbalances in the body. If this overdose is not treated with chelation therapy, it can lead to death or permanent coma.

Symptoms

Symptoms of overdose occur in various forms:

- Exaggerated form of normal action (sleepiness on antiepileptics, hypoglycemia on insulin)
- Other effects due to chemical properties of the medication (metabolic acidosis in aspirin, liver failure due to paracetamol)
- Non-specific symptoms due to central nervous system irritation (confusion, vertigo, nausea, vomiting)

Diagnosis

Diagnosis of an overdosed patient is generally straightforward if the drug is known. However, it can be very difficult if the patient cannot (or refuses to) state what drug they have overdosed on. At times, certain symptoms and signs exhibited by the patient, or blood tests, can reveal the drug in question. Even without knowing the drug, most patients can be treated with general supportive measures.

In some instances, empirical antidotes may be administered if there is sufficient indication that the patient has overdosed on a particular type of medication: naloxone in opioids and flumazenil in benzodiazepines. Rapid reversal of symptoms may serve as proof in these cases.

First aid

Medical disclaimer

Depressants

First aid can prevent a death from overdose of depressants as it may take several hours for someone to die in these cases. The common drugs in this category include opiates (ie. heroin, morphine and methadone), alcohol, and certain prescription drugs such as benzodiazepines. Signs of overdose are those of a depressed central nervous system — slow, infrequent or shallow breathing, blue lips or fingernails, cold or pale skin, slow or faint pulse, snoring or gurgling noises, and the inability to be woken from nodding off.

- The first step is to stay calm and see if you can get a response from the person by pinching the back of their arm, calling their name or rubbing your knuckles against their chest.
- If there is no response, check to make sure their airway is not blocked and see if they are breathing.
- See if they are breathing
- Roll them on to their side into the recovery position and perform cardiopulmonary resuscitation.[1]
- Call an ambulance. Ideally someone should call an ambulance immediately while another person evaluates the patient and attempts CPR. EMS personnel are not required by law to inform the police of drug overdoses, they usually do not inform the police as that would deter people from calling for help in an emergency.

Stimulants

People can overdose on stimulants, such as amphetamines, ecstasy and cocaine, too, with symptoms such as rapid heartbeat, muscle cramps, seizures, paranoia, psychosis, confusion, loss of control of movement, vomiting and lack of consciousness.

First aid in these cases involves staying with the person and helping them to remain calm. Move them to a quiet area, and where possible, apply a wet cloth to their neck or forehead. If unconscious, place them in the recovery position and call an ambulance.[1]

Prevention

- Be informed about any drugs you are taking.
- Do not take different types of illicit drugs together. [2]
- When you are unsure of a drug's strength, try a small dose first.
- Be aware of low tolerance following a period of abstinence (e.g. a period in detox or rehab or after leaving prison) when it comes to illicit drugs.

Causes

Common types of drugs that are overdosed on:

- Barbiturates

    - Seconal
    - Nembutal

- Narcotics
    - Heroin
- Stimulants
    - Cocaine
    - Methamphetamine
- Ethyl Alcohol
    - Alcoholic beverages
- Prescription drugs
    - drug "cocktails", or a combination of numerous drugs.

Drug resistance

Organisms are said to be *drug-resistant* when drugs meant to neutralize them have reduced effect. When an organism is resistant to more than one drug, it is said to be multidrug resistant. The most prominent example of this is antibiotic resistance. Drug resistance is also found in some tumor cells, which makes it more difficult to use chemotherapy to attack tumors made of those cells. When a drug such as an antibiotic is administered, those which have a genetic resistance to the drug will survive and reproduce, and the new population will be drug-resistant.

To counter drugs, bacteria and viral pathogens have evolved sophisticated mechanisms to inactivate these compounds (e.g. by pumping out compounds mutating residues required for the compound to bind etc.), and they do so at a rate that far exceeds the pace of new development of drugs. Examples include pan-drug resistant strains of Staphylococcus aureus, Klebsiella pneumonia, and Pseudomonas aerginosa, and Mycobacterium tuberculosis (TB) among bacterium and HIV-1 among viruses. Indeed, no new antibiotics have been developed against TB in thirty years. Efforts to develop new antibiotics by the

pharmaceutical industry by large-scale screens of chemical libraries which inhibit bacterial growth have largely failed, and new tetracycline and sulfanilamide analogs will likely engender resistance and will quickly be rendered useless. The resistance problem is compounded further by indiscriminate and inappropriate use of antibiotics and anti-viral compounds without compliance measures or public health policies to reduce disease burden. Finally, with current legislative restrictions, the astounding costs associated with clinical trials (e.g. ~$400M to bring new tetracyclines to market for an expected revenue of ~$100M), the failure to control generic sales, and the capacity to generate substantial revenues from medications for chronic illnesses, there is little if any financial incentive for big pharmaceutical companies to even develop new antibiotics, and small biotech companies simply do not have the resources. The search for novel anti-viral compounds has been somewhat more successful and largely motivated by the HIV pandemic, but drugs have been developed principally against viral targets, and mutation rates among viruses still outpaces new development. One positive development has been vaccines, which are promising for some bacterial and viral illnesses. But vaccines are not successful in all cases (e.g. in young children), and adequate resources have not been made available. In short, the lack of concerted effort by governments and the pharmaceutical industry, together with the innate capacity of microbes to develop resistance at a rate that outpaces development of new drugs, suggests that existing strategies for developing viable, long-term anti-microbial therapies are ultimately doomed to failure. Without alternative strategies, the acquisition of drug resistance by pathogenic microorganisms looms as possibly the single most significant public health threat facing humanity in the coming century.

Antipyretics

Antipyretics are drugs that prevent or reduce fever by lowering the body temperature from a raised state. However, they will not affect the normal body temperature if one does not have fever.

Antipyretics cause the hypothalamus to override an interleukin-induced increase in temperature. The body will then work to lower the temperature and the result is a reduction in fever.

Most are also used for other purposes. For example, the most common antipyretics in the United States are aspirin and acetaminophen, which are used primarily as pain relievers. There is some debate over the appropriate use of such medications: fever is part of the body's immune response to infection.

Herbal remedies with a fever-reducing effect are called *febrifuges*, and include catnip, chamomile, sage and yarrow. However, the term febrifuge can also refer to a refrigerant, such as topical alcohol, which cools the body by physically removing heat rather than modifying the body's responses.

Bisphosphonates

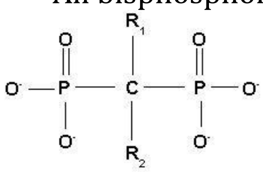
In pharmacology, *bisphosphonates* (also called: *diphosphonates*) is a class of drugs that inhibits the resorption of bone. Its uses include the prevention and treatment of osteoporosis, osteitis deformans ("Paget's disease of bone"), bone metastasis (with or without hypercalcemia), multiple myeloma and other conditions that feature bone fragility.

History

Bisphosphonates were developed in the 19th century, but were first investigated in the 1960s for use in disorders of bone metabolism. Their non-medical use included water softening in irrigation systems used in orange groves. The initial rationale for their use in humans was their potential in preventing the dissolution of hydroxylapatite, the principal bone mineral, and hence arresting bone loss. Only in the 1990s was their actual mechanism of action demonstrated.[1]

Chemistry and classes

All bisphosphonate drugs share a common P-C-P "backbone":



The two PO***3*** (phosphate) groups covalently linked to carbon determine both the name "bisphosphonate" and the function of the drugs.

The long side chain (*R*2 in the diagram) determines the chemical properties, the mode of action and the strength of bisphosphonate drugs. The short side chain (R***1***) mainly influences chemical properties and pharmacokinetics.

Pharmacokinetics

Of the bisphosphonate that is resorbed (from oral preparation) or infused (for intravenous drugs), about 50% is excreted unchanged by the kidney. The remainder has a very high affinity for bone tissue, and is rapidly absorbed onto the bone surface.

Mechanism of action

Bisphosphonates, when attached to bone tissue, are "ingested" by osteoclasts, the bone cell that breaks down bone tissue. The two types of bisphonates work differently in killing osteoclast cells.

There are two classes of bisphosphonate: the N-containing and non-N-containing bisphosphonates.

Agent	R_1 side chain	R_2 side chain
Etidronate	-OH	$-CH_3$
Clodronate	-Cl	-Cl
Tiludronate	-H	-S-  -Cl
Pamidronate	-OH	$-CH_2-CH_2-NH_2$
Neridronate	-OH	$-(CH_2)_5-NH_2$
Olpadronate	-OH	$-(CH_2)_2N(CH_3)_2$
Alendronate	-OH	$-(CH_2)_3-NH_2$
Ibandronate	-OH	$-CH_2-CH_2N$ $\langle$ CH_3 / $(CH_2)_4-CH_3$
Risedronate	-OH	Zoledronate	-OH	

Non-nitrogenous

Non-N-containing bisphosphonates:

- Etidronate (Didronel®) - 1 (potency relative to that of etidronate)
- Clodronate (Bonefos®, Loron®) - 10
- Tiludronate (Skelid®) - 10

The non-nitrogenous bisphosphonates are metabolised in the cell to compounds that compete with adenosine triphosphate (ATP) in the cellular energy metabolism. The osteoclast initiates apoptosis and dies, leading to an overall decrease in the breakdown of bone.[2]

Nitrogenous

N-containing bisphosphonates:

- Pamidronate (APD, Aredia®) - 100

Neridronate - 100
Olpadronate - 500
Alendronate (Fosamax®) - 500
Ibandronate (Bondronat®) - 1000
Risedronate (Actonel®) - 2000
Zoledronate (Zometa®) - 10000

Nitrogenous bisphosphonates act on bone metabolism by binding and blocking the enzyme farnesyl diphosphate synthase (FPPS) in the HMG-CoA reductase pathway (also known as the mevalonate pathway).[3]

Disruption of the HMG CoA-reductase pathway at the level of FPPS prevents the formation of two metabolites (farnesol and geranylgeraniol) that are essential for connecting some small proteins to the cell membrane. This phenomenon is known as prenylation, and is important for proper sub-cellular protein trafficking (see "lipid anchored protein" for the principles of this phenomenon).[4]

While inhibition of protein prenylation may affect many proteins found in an osteoclast, disruption to the lipid modifcation of Ras, Rho, Rac proteins has been speculated to underlie the effects of bisphosphonates. These proteins can affect both osteoclastogenesis, cell survival, and cytoskeletal dynamics. In particular, the cytoskeleton is vital for maintaining the "ruffled border" that is required for contact between a resorbing osteoclast and a bone surface.

Statins are another class of drugs that inhibit the HMG-CoA reductase pathway. Unlike bisphosphonates, statins do not bind to bone surfaces with high affinity, and are thus not specific for bone. Nevertheless, some studies have reported a decreased rate of fracture (an indicator of osteoporosis) and/or an increased bone mineral density in statin users. The overall efficacy of statins in the treatment osteoporosis remains controversial.

Uses

Bisphosphonates are used clinically for the treatment of osteoporosis, osteitis deformans (Paget's disease of the bone), bone metastasis (with or without hypercalcemia), multiple myeloma and other conditions that feature bone fragility.

In osteoporosis and Paget's, alendronate and risedronate are the most popular first-line drugs. If these are ineffective or the patient develops digestive tract problems, intravenous pamidronate may be used. Alternatively, strontium ranelate or teriparatide are used for refractory disease, and the SERM raloxifene is occasionally administered in postmenopausal women instead of bisphosphonates.

High-potency intravenous bisphosphonates have shown to modify progression of skeletal metastasis in several forms of cancer, especially breast cancer.

More recently, bisphosphonates have been used to reduce fracture rates in children with osteogenesis imperfecta.

Side-effects

- Oral bisphosphonates can give stomach upset and inflammation and erosions of the esophagus, which is the main problem of oral N-containing preparations. This can be prevented by remaining seated upright for 30 to 60 minutes after taking the medication.
- Intravenous bisphosphonates can give fever and flu-like symptoms after the first infusion. Notably, these symptoms do not recur with subsequent infusions.
- There is a slightly increased risk for electrolyte disturbances, but not enough to warrant regular monitoring.
- In chronic renal failure, the drugs are excreted much slower, and dose adjustment is required.
- Bisphosphonates have been associated with osteonecrosis of the jaw; with the mandible twice as frequently affected as the maxilla and most cases occurring following high-dose intravenous administration used for some cancer patients. Some 60% of cases are preceded by a dental surgical procedure and it has been suggested that bisphosphonate treatment should be postponed until after any dental work to eliminate potential sites of infection.[5]
- A number of cases of severe bone, joint or musculoskeletal pain have been reported, prompting labeling changes[6]

Dermatological preparations - Sunscreen

Sunscreen (also known as *sunblock*, *suntan lotion*) is a lotion, spray or other topical product that helps protect the skin from the sun's ultraviolet radiation, and which reduces sunburn and other skin damage, ultimately leading to a lower risk of skin cancer. However, suntan lotion is an incorrect term for sunscreen as it is something entirely different. Suntan lotion is used to attract UV rays in order to better tan where sunblock is used to deflect UV radiation. These are commonly called indoor tanning lotions when designed for use with tanning beds or just suntan lotion if designed for outdoor use and may or may not have SPF protection in them.

The best sunscreens protect against both UVB (ultraviolet radiation with wavelength between 290 and 320 nanometres), which can cause sunburn, and UVA (between 320 and 400 nanometres), which damages the skin with more long-term effects, such as premature skin aging. Most sunscreens work by containing either an organic chemical compound that absorbs ultraviolet light (such as oxybenzone) or an opaque material that reflects light (such as titanium dioxide, zinc oxide), or a combination of both. Typically, absorptive materials are referred to as chemical blocks, whereas opaque materials are mineral or physical blocks.

Dosing for sunscreen can be calculated using the formula for body surface area and subsequently subtracting the area covered by clothing. The dose used in FDA sunscreen testing is 2 mg/cm^2. From a sample calculation in a FDA monograph, if one assumes an "average" adult build of height 5 ft 4 in (163 cm) and weight 150 lb (68 kg) with a 32 in (82 cm) waist, that adult wearing a bathing suit covering the groin area should apply 29 g (approximately 1 oz) evenly to the uncovered body area.

Contrary to the common advice that sunscreen should be reapplied every 2–3 hours, research has shown that the best protection is achieved by application 15–30 minutes before exposure, followed by one reapplication 15–30 minutes after the sun exposure begins. Further reapplication is only necessary after activities such as swimming, sweating, and rubbing.[1]

However, more recent research at the University of California indicates that sunscreen needs to be reapplied within 2 hours in order to remain effective. Not reapplying could even cause more cell damage than not using sunscreen at all, due to the release of extra free radicals from the absorbed chemical.[2]

A significant reduction in sun exposure inhibits the production of vitamin D. However, excessive sun exposure has been conclusively linked to some forms of skin cancer and signs of premature aging. Recent studies have shown that vitamin D does not provide any protection from cancer. Season, geographic latitude, time of day, cloud cover, smog, skin type, and sunscreen all have an effect on vitamin D production in the skin, but fifteen minutes per day of direct exposure to the sun is a generally accepted guideline to follow for optimum vitamin D production. Experts generally recommend taking a fifteen minute walk in the morning or evening without wearing sunscreen to meet this requirement.

History

The ancient Greeks used olive oil as a type of sunscreen. However, this was not very effective. Throughout the early twentieth century, H.A. Milton Blake, a South Australian chemist, as well as several other inventors attempted to create an effective sunscreen but failed.

It was not until 1944 that the first effective sunscreen was invented. At that time, World War II was in full swing and many soldiers were getting serious sunburn. A pharmacist named Benjamin Greene decided to create something that would save the soldiers from the sun's harmful rays. In his wife's oven, he created a sticky, red substance which he called "red vet pet" (red veterinary petrolatum), which worked primarily by physically blocking the sun's rays with a thick petroleum-based product similar to Vaseline. Greene tested it on his own bald head. It did not work nearly as well as modern sunscreens, but it was a start.

Sunscreen has come a long way since its initial days. Modern products have much higher protection factors than Greene's sunscreen, and modern products can also be water- and sweat-resistant. But there are also negative effects. Some people rely too much on the product and do not understand the limitations of the sun protection factor (SPF); they assume that buying anything over SPF 30 will automatically prevent them getting burnt no matter how long they can stay in the sun. Too much sunbathing is one of the major causes of skin cancer across the world.

Addendum: An effective sunscreen had already been developed in 1938 by the Swiss chemistry student Franz Greiter, after he had severely burnt himself during an ascent of the Piz Buin on the border between Switzerland and Austria. He named his product, which he had developed in a small laboratory in his parents' home, Gletscher Creme or in English Glacier Cream. Still existing examples of the 'Glacier Cream' have shown to have a SPF of 2 and thus could be classed as an effective sunscreen.

Mechanism of action

The principal ingredients in sunscreens are usually aromatic molecules conjugated with carbonyl groups. This general structure allows the molecule to absorb high-energy ultraviolet rays and release the energy as lower-energy rays, thereby preventing the skin-damaging ultraviolet rays from reaching the skin. So, upon exposure to UV light, most of the ingredients (with the notable exception of avobenzone) do not undergo significant chemical change, allowing these ingredients to retain the UV-absorbing potency without significant photo-degradation.

Sun protection factor

The SPF (sun protection factor) of a sunscreen is a laboratory measure of the effectiveness of sunscreen; the higher the SPF, the more protection a sunscreen offers against UV-B (the ultraviolet radiation that causes sunburn) and UV-A (more associated with longer-term skin damage). The SPF indicates the time a person can be exposed to sunlight before getting sunburn with a sunscreen applied relative to the time he or she can be exposed

without sunscreen. For example, someone who would burn after 12 minutes in the sun would expect to burn after 2 hours (120 min) if protected by a sunscreen with SPF 10. In practice, the protection from a particular sunscreen depends on factors such as:

- The skin type of the user.
- The amount applied and frequency of re-application.
- Activities in which one engages (for example, swimming leads to a loss of sunscreen from the skin).
- Amount of sunscreen the skin has absorbed.

The SPF is an imperfect measure of skin damage because invisible damage and skin aging is also caused by the very common ultraviolet type A, which does not cause reddening or pain. Conventional sunscreen does not block UVA as effectively as UVB, and an SPF rating of 30+ may translate to significantly lower levels of UVA protection according to a 2003 study by RAFT trust-funded researchers. According to a 2004 study, UVA also causes DNA damage to cells deep within the skin, increasing the risk of malignant melanomas. Even some products labeled "broad-spectrum UVA/UVB protection" do not provide good protection against UVA rays [2]. The best UVA protection is provided by products that contain zinc oxide, avobenzone and mexoryl. Titanium dioxide probably gives good protection, but does not completely cover the entire UV-A spectrum[3].

Due to consumer confusion over the real degree and duration of protection offered, labeling restrictions are in force in several countries. In the United States in 1999, the Food and Drug Administration (FDA) decided to institute the labelling of SPF 30+ for sunscreens offering more protection, and a similar restriction applies in Australia. This was done to discourage companies making unrealistic claims about the level of protection offered (such as "all day protection"), and because an SPF over 30 does not provide significantly better protection

The SPF can be measured by applying sunscreen to the skin of a volunteer and measuring how long it takes before sunburn occurs when exposed to an artificial sunlight source. In the US, such an in vivo test is required by the FDA. It can also be measured in vitro with the help of a specially designed spectrometer. In this case, the actual transmittance of the sunscreen is measured, along with the degradation of the product due to being exposed to sunlight. In this case, the transmittance of the sunscreen must be measured over all wavelengths in the UV-B range (290–350 nm), along with a table of how effective various wavelengths are in causing sunburn (the erythemal action spectrum) and the actual intensity spectrum of sunlight (see the figure). Such in vitro measurements agree very well with in vivo measurements.

Mathematically, the SPF is calculated from measured data as

$$\mathrm{SPF} = \frac{\int A(\lambda)E(\lambda)d\lambda}{\int A(\lambda)E(\lambda)/\mathrm{MPF}(\lambda)\,d\lambda},$$

where E(») is the solar irradiance spectrum, A(») the erythemal action spectrum, and MPF(») the monochromatic protection factor, all functions of the wavelength ». The MPF is roughly the inverse of the transmittance at a given wavelength.

The above means that the SPF is not simply the inverse of the transmittance in the UV-B region. If that were true, then applying two layers of SPF 5 sunscreen would be equivalent to SPF 25 (5 times 5). The actual combined SPF is always lower than the square of the single-layer SPF.

The following are the FDA allowable active ingredients in sunblocks:

- p-Aminobenzoic acid (PABA) up to 15 %.

Avobenzone up to 3%.
Cinoxate up to 3%.
Dioxybenzone up to 3%.
Homosalate up to 15%.
Menthyl anthranilate up to 5%.
Octocrylene up to 10%.
Octyl methoxycinnamate (Octinoxate) up to 7.5%.
Octyl salicylate up to 5%.
Oxybenzone up to 6%.
Padimate O up to 8%.
Phenylbenzimidazole sulfonic acid (Ensulizole) up to 4%.
Sulisobenzone up to 10%.
Titanium dioxide up to 25%.
Trolamine salicylate up to 12 %.
Zinc oxide up to 25%.

Others include:

- 4-Methylbenzylidene camphor (USAN Enzacamene)

Tinosorb® M (USAN Bisoctrizole, INCI Methylene Bis-Benzotriazolyl Tetramethylbutylphenol)
Tinosorb® S (USAN Bemotrizinol, INCI Bis-Ethylhexyloxyphenol Methoxyphenyl Triazine)
Mexoryl® SX (USAN Ecamsule, INCI Terephthalylidene Dicamphor Sulfonic Acid)
Mexoryl® XL (INCI Drometrizole Trisiloxane)
Neo Heliopan® AP (INCI Disodium Phenyl Dibenzimidazole Tetrasulfonate)
Uvinul® A Plus (INCI Diethylamino Hydroxybenzoyl Hexyl Benzoate)
Uvinul® T 150 (INCI Octyl Triazone)
Uvasorb® HEB (INCI Diethylhexyl Butamido Triazone)
Parsol® SLX (INCI Polysilicone-15)

Most of these ingredients are not FDA approved, but all of them are approved within the EU. And some are permitted in other parts of the world as well. A lot of these relative new ingredients absorb UVA, making it easier for sunscreen manufacturers to formulate for the growing demand of sunscreens with better UVA protection.

Melanin

The hormone alpha-melanocyte stimulating hormone is made when the body is exposed to sunlight and is responsible for the development of the pigment melanin. Research is being

done to create stable artificial forms of the hormone. A promising candidate, melanotan, might be useful in the prevention of skin cancer, by causing tanning without the need for exposure to dangerous levels of UV.

Possible health effects

Recently, there has been increased attention to the possibility of adverse health effects associated with the synthetic compounds in most sunscreens. [5] A study published in April 1992, entitled "Could apples increase melanoma risk?" reported that the greatest increase in melanoma has occurred in those regions where sunscreen use is most prevalent.[4] Although one might believe that this effect is due to sunscreens being used more in regions where people are more exposed to UV light, this is not what is claimed by this study: Melanome incidence correlates strongly with the use of chemical sunscreens independently of the actual UV exposure.[5]

In a May 2006 report, "Nanomaterials, Sunscreens and Cosmetics: Small Ingredients, Big Risks", Friends of the Earth claimed that several types of nanoparticles (like titanium dioxide or zinc oxide) can be harmful to human tissue. Currently, there is no policy requiring mandatory product labelling on products that use these compounds.

Some individuals can have mild to moderate allergic reactions to certain ingredients in sunscreen, particularly the chemical benzophenone, which is also known as phenyl ketone, diphenyl ketone, or benzoylbenzene. It is not clear how much of benzophenone is absorbed into the bloodstream, but trace amounts can be found in urinalysis after use.

Endothelin receptor antagonists

A *endothelin receptor antagonist* (*ERA*) is a drug which blocks endothelin receptors. Two main kinds of ERAs exist: selective (e.g. sitaxsentan), which affect endothelin A, and dual ERAs, which affect both endothelin A and B (e.g. bosentan)

Glycoprotein IIb/IIIa inhibitors

In* medicine*, a* glycoprotein IIb/IIIa inhibitors*, also* GpIIb/IIIa inhibitors*, is class of* antiplatelet agents*.

Several GpIIb/IIIa inhibitors exist:

- abciximab (ReoPro®)
- eptifibatide (Integrilin®)
- tirofiban (Aggrastat®)

Use

Glycoprotein IIb/IIIa inhibitors are frequently used during percutaneous coronary interventions (angioplasty with or without intracoronary stent placement).

They work by preventing platelet aggregation and thrombus formation. They do so by inhibition of the GpIIb/IIIa receptor on the surface of the platelets.

History

Their development arose from the understanding of Glanzmann's thrombasthenia, a condition in which the GpIIb/IIIa is lacking.[1]

Ointments

An *ointment* is a viscous semisolid preparation used topically on a variety of body surfaces. These include the skin and the mucus membranes of the eye (an eye ointment), vagina, glans and nose. An ointment may or may not be medicated.

Related topical preparations include creams, lotions, liniments and gels.

Ointments generally are inexpensive to purchase.

Orphan drugs

The granting of the *orphan drug* status is designed to encourage the development of drugs which are necessary but would be prohibitively expensive/un-profitable to develop under normal circumstances.

In the United States, an orphan drug is any drug developed under the Orphan Drug Act of January 1983 ("ODA"), a federal law concerning rare diseases ("orphan diseases"), defined as diseases affecting fewer than 200,000 people in the United States or low prevalence is taken as prevalence of less than 5 per 10,000 in the community. This has been adopted as a subclause of the Food and Drug Administration (FDA) regulations. Because medical research and development of drugs to treat such diseases is financially disadvantageous, companies that do so are rewarded with tax reductions and marketing exclusivity, or a monopoly, on that drug for an extended time (twenty years). The concept behind the ODA is that the longer period of exclusivity will encourgage more companies to invest money in research. Under the act many drugs have been developed, including drugs to treat glioma, multiple myeloma, cystic fibrosis, and snake venom. In the US, from January 1983 to June 2004, a total of 1,129 different orphan drug designations have been granted by the Office of Orphan Products Development (OOPD) and 249 orphan drugs have received marketing authorisation in the US. In contrast, the decade prior to 1983 saw fewer than ten such products come to market.

A similar status exists in the European Union, administered by the Committee on Orphan Medicinal Products of the European Medicines Agency.

In 2003, the leading orphan drug by worldwide sales revenue was Amgen's Erythropoietin (Epogen®), with sales of $2.4bn.

Development of orphan drugs

Since few markets would naturally exist to create these goods, as the costs of developing, researching and producing this drug would likely exceed any revenues, government intervention is required, usually to establish such a market or to produce the goods itself. Critics of the free market often cite this as a market failure in free market economic systems. Free market advocates often respond that without government intervention development costs would be considerably lower.

The intervention by government can take a variety of forms:

- Tax benefits to companies who produce or research these drugs
- Granting of additional rights above and beyond those granted by the regular patent laws.
- Subsidizing and funding clinical research by universities and industry sponsors to develop medical products (including drugs, biological products, devices, and medical foods) for rare diseases.
- Creating a government-run company to research and produce drugs for an example of this type of solution).

Patent medicine

Patent medicine is the term given to various medical compounds sold under a variety of names and labels, though they were for the most part actually trademarked medicines, not patented. In ancient times, such medicine was called *nostrum remedium*, "our remedy" in Latin, hence the name "nostrum"; it is a medicine whose efficacy is questionable and whose ingredients are usually kept secret. The name patent medicine has become particularly associated with the sale of drug compounds in the nineteenth century under cover of colourful names and even more colourful claims. The promotion of patent medicines was one of the first major products of the advertising industry, and many advertising and sales techniques were pioneered by patent medicine promoters. Patent medicine advertising often talked up exotic ingredients, even if their actual effects came from more prosaic drugs. One memorable group of patent medicines — liniments that allegedly contained snake oil, supposedly a universal panacea — made snake oil salesman a lasting synonym for a charlatan.

Patent medicines and advertising

The phrase patent medicine comes from the early days of the marketing of medical elixirs, when those who found favour with royalty were issued letters patent authorising the use of the royal endorsement in advertising. The name stuck well after the American Revolution made these endorsements by the crowned heads of Europe obsolete. Few if any of the nostrums were actually patented; chemical patents came into use in the USA in 1925, and in any case attempting to monopolize a drug, medical device, or medical procedure was considered unethical by the standards upheld during the era of patent medicine.

Instead, the compounders of these nostrums used a primitive version of branding to distinguish themselves from the crowd of their competitors. Many familiar names from the era live on in brands such as Luden's cough drops, Lydia E. Pinkham's vegetable compound for women, Fletcher's Castoria, and even Angostura bitters, which was once marketed as a stomach remedy. Many of these medicines, though sold at high prices, were made from quite cheap ingredients. Their composition was well known within the pharmacy trade, and druggists would sell (for a slightly lower price) medicines of almost identical composition that they had manufactured themselves. To protect profits, the branded medicine advertisements laid great emphasis on the brand-names, and urged the public to accept no substitutes.

At least in the earliest days, the history of patent medicines is coextensive with the history of medicine itself. Empirical medicine, and the beginning of the application of the scientific method to medicine, began to yield a few effective herbal and mineral drugs for the physician's arsenal. These few tested and true remedies, on the other hand, were inadequate to cover the bewildering variety of diseases and symptoms. Beyond these patches of knowledge they had to resort to occultism; the "doctrine of signatures" — essentially, the application of sympathetic magic to pharmacology — held that nature had hidden clues to medically effective drugs in their resemblances to the human body and its parts. This led medical men to hope, at least, that, say, walnut shells might be good for skull fractures. Given

the state of the pharmacopoeia, and patients' demands for something to take, physicians began making "blunderbuss" concoctions of various drugs, proven and unproven. These concoctions were the ancestors of the several nostrums.

Touting these nostrums was one of the first major projects of the advertising industry. The marketing of nostrums under implausible claims has a long history. In Henry Fielding's Tom Jones (1749), allusion is made to the sale of medical compounds claimed to be universal panaceas:

As to Squire Western, he was seldom out of the sick-room, unless when he was engaged either in the field or over his bottle. Nay, he would sometimes retire hither to take his beer, and it was not without difficulty that he was prevented from forcing Jones to take his beer too: for no quack ever held his nostrum to be a more general panacea than he did this; which, he said, had more virtue in it than was in all the physic in an apothecary's shop.

Within the English-speaking world, patent medicines are as old as journalism. "Anderson's Pills" were first made in England in the 1630s; the recipe was allegedly learned in Venice by a Scot who claimed to be physician to King Charles I. The use of letters patent to obtain exclusive marketing rights to certain labelled formulas and their marketing fueled the circulation of early newspapers. The use of invented names began early. In 1726 a patent was also granted to the makers of "Dr. Bateman's Pectoral Drops"; at least on the documents that survive, there was no Dr. Bateman. This was the enterprise of a Benjamin Okell and a group of promoters who owned a warehouse and a print shop to promote the product.

A number of American institutions owe their existence to the patent medicine industry, most notably a number of the older almanacs, which were originally given away as promotional items by patent medicine manufacturers. Perhaps the most successful industry that grew up out of the business of patent medicine advertisements, though, was founded by William H. Gannett in Maine in 1866. There were few circulating newspapers in Maine in that era, so Gannett founded a periodical, Comfort, whose chief purpose was to propose the merits of Oxien, a nostrum made from the fruit of the baobab tree, to the rural folks of Maine. Gannett's newspaper became the first publication of the Gannett Corporation, whose flagship newspaper today is USA Today.

Another method of publicity undertaken mostly by smaller firms was the "medicine show," a travelling circus of sorts which offered vaudeville-style entertainments on a small scale, and which climaxed in a pitch for the nostrum being sold. Muscleman acts were especially popular on these tours, for this enabled the salesman to tout the physical vigour offered by the potion he was selling. The showmen frequently employed shills, who would step forward from the crowd and offer "unsolicited" testimonials about the benefits of the medicine for sale. Oftentimes, the nostrum was manufactured and bottled in the same wagon that the show travelled in. The Kickapoo Indian Medicine Company became one of the largest and most successful medicine show operators; their shows had an American Indian or Wild West theme, and employed many Native Americans as spokespeople. The medicine show lived on in American folklore and Western movies long after they had vanished from public meeting places.

Ingredients and their uses

What did the sellers claim as ingredients?

Some level of exoticism and mystery in the contents of the preparation was deemed desirable by their promoters. Unlikely ingredients such as the baobab fruit in Oxien were a recurring theme. A famous patent medicine of the period was Dr. Kilmer's Swamp Root; unspecified roots found in swamps had remarkable effects on the kidneys, according to its literature.

Native American themes were also useful; Natives, imagined to be noble savages, were thought to be in tune with Nature, and heirs to a body of traditional lore about herbal remedies and natural cures. One example of this approach from the period was Kickapoo Indian Sagwa, a product of the Kickapoo Indian Medicine Company of Connecticut (completely unrelated to the real Kickapoo Indian tribe of Oklahoma), supposedly based on a Native American recipe. This nostrum was the inspiration for Al Capp's "Kickapoo Joy Juice," featured in the comic strip, "Li'l Abner".

Other promoters took an opposite tack from timeless herbal wisdom. Just about any scientific discovery or exotic locale could be used as a key ingredient in a patent medicine. Consumers were invited to invoke the power of electromagnetism to heal their ailments. In the nineteenth century, electricity and radio were gee-whiz scientific advances that found their way into patent medicine advertising, especially after Luigi Galvani showed that electricity influenced the muscles. Devices meant to electrify the body were sold; nostrums were compounded that purported to attract electrical energy or make the body more conductive. Albert Abrams was a well known practitioner of electrical quackery, claiming the ability to diagnose and treat diseases over long distances by radio.

Towards the end of the period, a number of radioactive medicines, containing uranium or radium, were marketed. These apparently actually contained the ingredients promised, and there were a number of tragedies among their devotees; most notoriously, Eben McBurney Byers, a steel heir, a supporter of the popular radium water "Radithor", who contracted radium poisoning and had to have his jaw removed after taking more than a thousand bottles of "radium water." Water irradiators were sold that promised to infuse water placed within them with radon, which was thought to be healthy at the time.

What did they actually contain?

While various herbs, touted or alluded to, were talked up in the advertising, their actual effects often came from opium extracts, cocaine, or grain alcohol. Those containing opiates were at least effective in relieving pain, though they could result in addiction. This hazard was sufficiently well known that many were advertised as causing none of the harmful effects of opium (though many of those so advertised actually did contain opium) In the case of medicines for "female complaints", the principal "Female complaint" that the medicine was intended to treat was early pregnancy; such products contained ingredients capable of causing abortion, such as pennyroyal, tansy or savin.

Until the twentieth century alcohol was the most controversial ingredient; for it was widely recognised that the "medicines" could continue to be sold for their alleged curative properties even in prohibition states and counties. Many of the medicines were in fact liqueurs of various sorts, flavoured with herbs said to have medicinal properties. Peruna was a famous "Prohibition tonic," weighing in at around 18% grain alcohol. A nostrum known as "Jamaica ginger" was ordered to change its formula by Prohibition officials; to fool a chemical test, some vendors added a toxic chemical, cresyl phosphate, an organophosphate compound that had effects similar to a nerve agent. Unwary imbibers suffered a form of paralysis that came to be known as jake-leg. Some included laxatives such as senna or diuretics, in order to give the compounds some obvious medical effects. The narcotics and stimulants at least had the virtue of making the people who took them feel better, and in the eyes of the advertisers this was scored as a "cure."

Clark Stanley the "Rattlesnake King" produced Stanley's snake oil, publicly processing rattlesnakes at the World's Columbian Exposition in Chicago. His liniment, when seized and tested by the federal government in 1917, was found to contain mineral oil, 1% fatty oil, red pepper, turpentine and camphor. This is not too unlike modern capsaicin and camphor liniments.

When journalists and physicians began focusing on the narcotic contents of the patent medicines, some of their makers began substituting acetanilide, a particularly toxic non-steroidal anti-inflammatory drug, discovered in 1886, for the laudanum they used to contain. This ingredient change probably killed more of the nostrum's users than the narcotics did, since the acetanilide was toxic to the liver and kidneys.

What did they claim to be good for?

What were they supposed to be good for? Just about everything. Nostrums were openly sold that claimed to cure or prevent venereal diseases, tuberculosis, and cancer. Bonnore's Electro Magnetic Bathing Fluid claimed to cure cholera, neuralgia, epilepsy, scarlet fever, necrosis, mercurial eruptions, paralysis, hip diseases, chronic abscesses, and "female complaints." A panacea so universally effective cannot be bought today at any price. William Radam's Microbe Killer, a product sold widely on both sides of the Atlantic in the 1890s and early 1900s, had the bold claim 'Cures All Diseases' prominently embossed on the front of the bottle. Ebeneezer Sibley ('Dr Sibley') in late 18th and early 19th century Britain went so far as to advertise that his Solar Tincture was able to "restore life in the event of sudden death", amongst other marvels.

Every manufacturer published long lists of testimonials in which all sorts of human ailments were cured by the compounds. Fortunately for both their makers and users, the illnesses that they claimed were cured were almost invariably self-diagnosed, and the claims of the writers to have been healed of cancer or tuberculosis by the nostrum should be considered in this light. In fact many, if not most, patent medicines were products of quackery, and were of little or no therapeutic benefit.

The end of the patent medicine era

Muckraker journalists and other investigators began to publicize instances of death, drug addiction, and other hazards from the compounds. This took some small courage on behalf of the publishing industry that circulated these claims, since the typical newspaper of the period relied heavily on the patent medicines, which founded the U.S. advertising industry. In 1905, Samuel Hopkins Adams published an exposé entitled "The Great American Fraud" in Collier's Weekly that led to the passage of the first Pure Food and Drug Act in 1906. This statute did not ban the alcohol, narcotics, and stimulants in the medicines; it required them to be labelled as such, and curbed some of the more misleading, overstated, or fraudulent claims that appeared on the labels. In 1936 the statute was revised to ban them, and the United States entered a long period of ever more drastic reductions in the medications available unmediated by physicians and prescriptions.

The patent medicine makers moved from selling nostrums to selling deodorants and toothpastes, which continued to be advertised using the same techniques that had proven themselves selling nostrums for tuberculosis and "female complaints." One survival of the herbal exoticism that once characterized the patent medicine industry is the marketing of shampoos, which are often promoted as containing perfumes such as vetivert or ylang-ylang, and foods such as mangoes, bananas, or honey; consumers are urged to put these ingredients in their hair.

In more recent years, also, various herbal concoctions have been marketed as "nutritional supplements". While their advertisements are careful not to cross the line into making explicit medical claims, and often bear a disclaimer that asserts that the products have not been tested and are not intended to diagnose or treat any disease, they are nevertheless marketed as remedies of various sorts. Weight loss and similar claims are frequently found on these compounds. One of the most notorious such elixirs, however, calls itself "Enzyte", widely advertised for "natural male enhancement" — that is, penis enlargement. Despite being a compound of herbs, minerals, and vitamins, Enzyte formerly promoted itself under a fake scientific name Suffragium asotas. Enzyte's makers translate this phrase as "better sex," but it is in fact ungrammatical Latin for "refuge for the dissipated."[1]

Surviving consumer products from the patent medicine era

A number of brands of consumer products that date from the patent medicine era are still on the market and available today. Their ingredients may have changed from the original formulas; the claims made for the benefits they offer have typically been seriously revised. These brands include:

- 666 Cold Medicine

Absorbine Jr.
BC Powder
Bromo-Seltzer
Carter's Little Liver Pills (Currently sold as Carter's Little Pills)
Chlorodyne
Doan's Pills

Fletcher's Castoria
Geritol
Goody's Powder
Lobeila Cough Syrup
Luden's Throat Drops
Phillips' Milk of Magnesia
Lydia E. Pinkham's Vegetable Compound
Smith Brothers Throat Drops
Vicks VapoRub

A number of patent medicines are produced in China; among the best known of these is Shou Wu Chih, a black, alcoholic liquid which is claimed to turn gray hair black.

Products no longer sold under medicinal claims

Some consumer products were once marketed as patent medicines, but have been repurposed and are no longer sold for medicinal purposes. Their original ingredients may have been changed to remove drugs, such is the case with Coca-Cola. The compound may also simply be used in a different capacity, as in the case of Angostura Bitters, now associated chiefly with cocktails.

- Angostura Bitters

Bovril
Coca-Cola
Dr Pepper
Hires Root Beer
Moxie brand soda

- tonic water

Pyrazole

Chemical name Pyrazole

Chemical formula $C_3H_4N_2$

Synonyms 1,2 diazole, Pyrazol

Molecular mass 68.07 g/mol

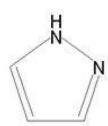
Melting point 66-70 °C

Boiling point 186-188 °C

Density x.xxx g/cm3

CAS number 288-13-1

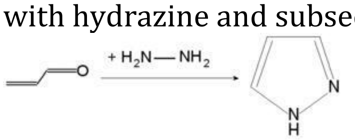
SMILES C1=CC=NN1



Disclaimer and references

Pyrazole refers both to the class of simple aromatic ring organic compounds of the heterocyclic series characterized by a 5-membered ring structure composed of three carbon atoms and two nitrogen atoms in adjacent positions and to the unsubstituted parent compound. Being so composed and having pharmacological effects on humans, they are classified as alkaloids although they are not known to occur in nature.

Pyrazoles are produced synthetically through the reaction of ±,^{2}-unsaturated aldehydes with hydrazine and subsequent dehydrogenation.



Pyrazoles are used for their analgesic, anti-inflammatory, antipyretic, antiarrhythmic, tranquilizing, muscle relaxing, psychoanaleptic, anticonvulsant, monoamineoxidase inhibiting, antidiabetic and antibacterial activities.

Structurally related compounds are pyrazoline and pyrazolidine.

Pyrazolopyrimidines

The *Pyrazolopyrimidines* are a class of nonbenzodiazepine drugs related (in terms of their effect) to benzodiazepines.

These drugs are intended to induce sleep, and are prescribed for people suffering insomnia.

They include:

- Zaleplon as Sonata ®

Indiplon ®

Insecticide

A related use is in pyrazolopyrimidine organothiophosphate insecticides.

Structure

The molecules are typified by the linked six sided (benzene) and sometimes five sided rings (methylpyrazol).

Drugs in sport

In sports, *doping* refers to the use of performance-enhancing drugs such as anabolic steroids, particularly those that are forbidden by the organizations that regulate competitions. Some doping substances, however, are permitted in low doses (alcohol and caffeine). Another form of doping is blood doping, either by blood transfusion or use of the hormone erythropoietin (EPO). Also considered "doping" by many is the use of substances that mask other forms of doping.

Currently, tetrahydrogestrinone (THG) and modafinil are causing controversy throughout the sporting world, with many high profile cases attracting major press coverage as prominent United States athletes have tested positive for these doping substances. Some athletes who were found to have used modafinil protested as the drug was not on the prohibited list at the time of their offence; however, the World Anti-Doping Agency (WADA) maintains it is a substance related to those already banned, so the decisions stand. Modafinil was added to the list of prohibited substances on August 3, 2004, ten days before the start of the 2004 Summer Olympics.

In recent years, gene doping has been reported as being an emerging form of doping. Gene doping would be very difficult to detect and when used it will last for many years.

Reaction from sports organizations

The International Amateur Athletic Federation, now the International Association of Athletics Federations, were the first international governing body of sport to take the situation seriously. In 1928 they banned participants from doping, but with little in the way of testing available they had to rely on the word of the athlete that they were clean.

It was not until 1966 that FIFA (soccer) and Union Cycliste Internationale (cycling) joined the IAAF in the fight against drugs, closely followed by the International Olympic Committee the following year.

Progression in pharmacology has always outstripped the ability of sports federations to implement rigorous testing procedures but since the creation of the World Anti-Doping Agency in 1999 more and more athletes are being caught.

The first tests for athletes were at the 1966 European Championships and two years later the IOC implemented their first drug tests at both the Summer and Winter Olympics. Anabolic steroids became prevalent during the 1970s and after a method of detection was found they were added to the IOC's prohibited substances list in 1976.

A handful of commentators maintain that as outright prevention of doping is an impossibility, and that all doping should be legalised. However, most disagree with this assertion, pointing out the harmful long-term effects of many doping agents. With doping legal, all competitive athletes would be compelled to use drugs, the net effect would be a level playing field but with widespread health consequences.

Another point of view is that doping could be legalized to some extent using a drug whitelist and medical counseling, such that medical safety is ensured, with all usage published. However, under such a system, it is likely that athletes would cheat by exceeding official limits to try to gain an advantage, policing such a system would be as difficult as policing a total ban on performance enhancing drugs.

Notable drug scandals and use in professional sport

The first recorded attempt to enhance performance occurred as early as the 8th century BC, when Ancient Greek Olympians ate sheep's testicles; today we would recognize these as a source of testosterone.

As early as the late 19th century professional cyclists were using substances like caffeine, cocaine and ether-coated sugar cubes to improve performance, reduce pain and delay fatigue.

In the 1904 Olympics, Thomas Hicks (USA) won the marathon at St. Louis and collapsed. It took hours to revive him; he had taken brandy mixed with strychnine to help him win his gold medal.

Nazi Germany athletes were rumored to use the first rudimentary testosterone preparations in the 1936 Summer Olympics.

World Weightlifting Championships of 1954 was the first unconfirmed testosterone injections by Soviet Athletes doping attempt ending in the Soviets winning the gold medal in most weight classes and breaking several world records.

In early 1960s Dr. John Ziegler (who was the US Team Coach in the 1954 Soviet-dominated World Weightlifting Championships) administered his weightlifters Dianabol tablets and the US dominated the 1962 World Championships.

In 1965 Dutch swimmers used stimulants.

During the 1967 Tour de France, Tom Simpson collapsed during the ascent of the Mont Ventoux. Despite mouth-to-mouth resuscitation and the administration of oxygen, plus a helicopter airlift to a nearby hospital, Simpson died. Two tubes of amphetamines and a further empty tube were found in the rear pocket of his racing jersey.

A famous case of illicit drug use in a competition was Canadian Ben Johnson's victory in the 100 m at the 1988 Summer Olympics. He subsequently failed the drug test when stanozolol was found in his urine. He later admitted to using the steroid as well as Dianabol, Cypionate, Furazabol, and human growth hormone amongst other things. Carl Lewis was then promoted one place to take the Olympic gold title. Later it was revealed that he also had been using drugs.

In the 1970s and 1980s, many athletes from Eastern bloc nations were suspected to be augmenting their ability with some kind of pharmacological help. After the fall of communism in Eastern Europe and the reunification of Germany, documents surfaced proving that the East German sport establishment had conducted systematic doping of virtually all of its world-class athletes.

In 1998 the entire Festina team were excluded from the Tour de France following the discovery of a team car containing large amounts of various performance-enhancing drugs. The team director later admitted that some of the cyclists were routinely given banned substances. Six other teams pulled out in protest including Dutch team TVM who left the tour still being questioned by the police. The Festina scandal overshadowed cyclist Marco Pantani's tour win, but he himself later failed a test. More recently David Millar, the 2003 World-Time Trial Champion, admitted using EPO, and was stripped of his title and suspended for two years. Still later, Roberto Heras was stripped of his victory in the 2005 Vuelta a España and suspended for two years after testing positive for EPO.

In July 2005, founders of California's Bay Area Laboratory Co-operative pleaded guilty to steroid distribution and money laundering. Those implicated or accused in the ensuing scandal include athletes Dwain Chambers, C.J. Hunter, Marion Jones and Tim Montgomery, baseball players Barry Bonds, Jason Giambi and Gary Sheffield, and several members of the Oakland Raiders.

At the 2006 Winter Olympics, Walter Mayer fled from the police when, acting on a tip, the Italian authorities conducted a surprise raid to search for evidence of doping.

The 2006 book Game of Shadows alleges extensive use of several types of steroids and growth hormone by baseball superstar Barry Bonds, and also names several other athletes as drug cheats.

In 2006, Spanish police arrested five people, including the sporting director of the Liberty Seguros cycling team, on charges of running a massive doping scheme involving most of the team and many other top cyclists. Several potential contenders in the 2006 Tour de France were forced to withdraw when they were linked to the scheme. For more details, see Operación Puerto doping case.

Less than a week after the 2006 Tour de France it was revealed that winner Floyd Landis had tested positive for an elevated testosterone/epitestosterone ratio (with normal levels of testosterone and deficient levels of epitestosterone) after his stunning stage 17 victory. Secondary tests have also confirmed the preliminary findings of deficient levels of epitestosterone resulting in a skewed T/E ratio, and a decision to strip him of the title is currently pending.

On July 29, another American champion failed a drug test - Olympic and world 100-meter champion Justin Gatlin.

In September 2006, Some former teammates of Cyclist Lance Armstrong admitted to taking EPO during the 1999 Tour de France. While they did not state that Armstrong had done the same, the article printed did attack Armstrong, who throughout his carrer has been a target of doping alligations, mainly stemming from his recovery from cancer and eventually winning a record seven straight Tour de France titles.

Sympathomimetics

Sympathomimetics are a class of drugs whose effects mimic those of a stimulated sympathetic nervous system. As such they increase cardiac output, dilate bronchioles, and usually produce constriction of blood vessels. Sympathomimetics include the naturally occurring substances such as adrenaline (epinephrine), noradrenaline (norepinephrine), dopamine, ephedrine, and cocaine, as well as the synthetic drugs pseudoephedrine, phenylephrine, phenylpropanolamine, Amphetamine and methamphetamine, among others.

In medicine, certain sympathomimetics are commonly prescribed in cardiac emergencies including shock, asthma and anaphylaxis, in some cases for weight loss, and in cold remedies, where they shrink swollen membranes in the upper respiratory tract.

In recent years, phenylpropanolamine has been removed from over-the-counter cold formulations after it was implicated in causing an increased risk of hemorrhagic stroke.

Tocolytics

Tocolytics are medications used to suppress premature labor (toco refers to contractions, and lytic to removal). They are nearly always given in midpregnancy during preterm labor, when delivery would result in an extremely premature infant. This therapy is mainly instituted so that administration of glucocorticoids (which accelerate fetal lung maturity) can begin.

During administration of tocolytic medications, the mother's condition and the fetal heart rate pattern will be closely monitored by a health care professional to determine effects the medication is having on the mother and fetus' well being. If medication as well as other interventions fail to have the desired effect, immediate cesarian delivery may be required. Tocolytic therapy can delay birth by up to several days at its best.

Types of agents

Various types of agents are used, with varying success rates and side effects. Some medications are not FDA approved specifically for use in stopping uterine contractions in preterm labor, but are still used off label. Magnesium sulfate is the most commonly used tocolytic agent.

Examples:

- $MgSO_4$
  - Ritodrine (Yutopar)

  Fenoterol
  Nifedipine (Procardia, Adalat)
  Atosiban
  Indomethacin
  Terbutaline (Brethine)

Ethyl alcohol was frequently prescribed as a tocolytic in the mid-20th century, but later double-blind studies[1] have not shown it to be effective.

Contraindications to Tocolysis

Several factors may contraindicate delaying birth with the use of tocolytic medications. [2]

- Fetus is older than 37 weeks gestation

Fetus weighs more than 2500g or has IUGR
Fetus is in acute distress or has passed (or has a fatal anomaly)
Dilation is greater than 4 cm
Chorioamnionitis or intrauterine infection is present
Mother has severe PIH, eclampsia, active vaginal bleeding, a cardiac disease, or another condition which indicates that the pregnancy should not continue.

Triptans

Triptans are a family of tryptamine drugs used as abortive medication in the treatment of migraine and cluster headaches. They were first introduced in the 1990s. While effective at treating individual headaches, they are neither a preventative nor a cure. Their action is attributed to their binding to serotonin 5-HT1B and 5-HT1D receptors in cranial blood vessels (causing their constriction) and subsequent inhibition of pro-inflammatory neuropeptide release.

A test measuring a person's skin sensitivity during a migraine may indicate whether the individual will respond to treatment with triptans. Triptans are most effective in those with no skin sensitivity; with skin sensitivity, it is best to take triptans within twenty minutes of the headache's onset.

Triptans include sumatriptan (Imitrex, Imigran), rizatriptan (Maxalt), naratriptan (Amerge, Naramig), zolmitriptan (Zomig), eletriptan (Relpax), almotriptan (Axert, Almogran), and frovatriptan (Frova, Migard).

Vasodilators

Vasodilation is where blood vessels in the body become wider following the relaxation of the smooth muscle in the vessel wall. This will reduce blood pressure - since there is more room for the blood. The opposite physiological process is vasoconstriction.

Vasomotor refers to the muscles and nerves controlling the process of vasodilation.

A *vasodilator* is a substance that causes vasodilation. Several vasodilators are used as drugs which may, for example, allow blood to flow more easily around a clot.

Flushing may be a physiological response to vasodilators.

Natural vasodilators and Drugs that Exploit Them

- Absence of high levels of environmental noise

- Adenosine
  - Adenocard - this is primarily used as an anti-arrhythmic.
- Adrenaline and noradrenaline vasodilate arterioles of the skeletal muscles. (By acting on beta-2 adrenergic receptors.) These chemicals cause vasoconstriction elsewhere.
  - Alpha blockers (block the constricting effect of adrenaline).
- L-Arginine

Atrial natriuretic peptide (ANP) - a weak vasodilator.
Bradykinin
Endothelium-derived hyperpolarizing factor (EDHF)

- Histamine
  - Complement proteins C3a, C4a and C5a work by triggering histamine release from mast cells and basophil granulocytes.
- Niacin (aka nicotinic acid)
- Nitric oxide
  - Glyceryl trinitrate (commonly known as Nitroglycerin)
  Isosorbide mononitrate & Isosorbide dinitrate
  Pentaerythritol Tetranitrate (PETN)
  Sodium nitroprusside
  - PDE5 inhibitors: these agents indirectly increase the effects of nitric oxide
    - Sildenafil
    - Tadalafil
    Vardenafil
- Platelet activating factor (PAF)

Prostacyclin (PGI2) as well as other prostaglandins.

- Tetrahydrocannabinol (THC) - the major active chemical in marijuana. Its mild vasodilating effects redden the eyes of cannabis smokers.
- Papaverine an alkaloid found in the opium poppy papaver somniferum

Erythropoietin (IPA pronunciation: [jÌyj¸.yoÈpo.j.tjn], alternative pronunciations: [jÌrj¸roŠÈpTjtn, YÌrj¸roŠ-, YÌri¸roŠ-]) or *EPO* is a glycoprotein hormone that is a cytokine for erythrocyte (red blood cell) precursors in the bone marrow. Also called hematopoietin or hemopoietin, it is produced by the kidney, and is the hormone regulating red blood cell production. Erythropoietin is available as a therapeutic agent produced by recombinant DNA technology in mammalian cell culture. It is used in treating anemia resulting from chronic renal failure or from cancer chemotherapy. Its use is also believed to be common as a blood doping agent in endurance sports such as bicycle racing, triathlons and marathon running.

Discovery and biological role

The existence of a humoral factor regulating red blood cell production was first postulated in 1906 based on transfusion experiments in rabbits. In 1950, the still unidentified erythropoietic factor was found to be stimulated in rats breathing a low-oxygen atmosphere, thus establishing the elements of its biological regulation. In the 1960s its source was identified as the kidneys. Human EPO was first purified from human urine by T. Miyake, C. K. Kung and E. Goldwasser at the University of Chicago in 1977. Limited quantitites of the native human protein were used experimentally to treat patients with anemia.

EPO has now been identified as a glycoprotein with a molecular mass of about 30,000 Daltons. It has a 165 amino acid chain with four oligosaccharide side chains and circulates in the blood plasma at a very low concentration (about 5 pmol/L).

In adult humans, EPO is produced primarily by peritubular cells in the kidneys, where its production is stimulated by low oxygen levels in the blood, also known as hypoxia. Some EPO is also produced by the liver, which is the primary source in the fetus.

EPO acts by binding to a specific erythropoietin receptor (EpoR) on the surface of red cell precursors in the bone marrow, stimulating them to transform into mature red blood cells. As a result the oxygen level in blood reaching the kidney rises and the amount of EPO produced decreases.

Because the kidneys are the primary source of erythropoietin, chronic kidney disease often results in a systemic deficiency of EPO and consequent anemia. Anemia can also occur in cancer patients, sometimes as a direct result of the malignancy but usually as an adverse effect of chemotherapy.

Also, in patients who may require a blood transfusion or undergo surgery where blood loss is expected, EPO is given in advance as a precaution. The bone marrow produces more red blood cells, and if blood is lost during the operation, there is still enough to sustain the patient.

EPO as a therapeutic agent

Therapeutic human erythropoietin was initially isolated and purified from urine in 1977. In 1983, the gene coding for erythropoietin was identified by a team headed by Fu-Kuen Lin at U.S. biotechnology company Amgen. Researchers at The Genetics Insitute (now part of Wyeth) independently discovered the gene at approximately the same time. The resulting patent dispute led to Amgen gaining exclusive marketing rights for erythropoietin in the U.S. Recombinant DNA technology was used to express the protein in Chinese hamster ovary cells, which allowed a synthetic form of EPO (rEPO) to be produced in commercial quantities for the first time.

Recombinant EPO was launched as a pharmaceutical product by Amgen for treatment of anemia resulting from chronic renal failure in 1989 under the brand name Epogen. In 1991 it was also approved for treating anemia resulting from cancer chemotherapy. However, recent clinical studies on patients with head and neck squamous cell carcinoma (HNSCC) and breast carcinoma, in addition to relevant basic science research have demonstrated that patients whose tumors are positive for the erythropoietin receptor (EpoR) may be at increased risk of tumor progression (metastatic spread) if treated with Epo. Johnson & Johnson (J&J), an American pharmaceutical company, markets EPO under license from Amgen for cancer chemotherapy under the brand name Procrit. Amgen's patents have so far prevented other companies from entering the U.S. market. Even though the patents are all based on work done in the early 1980s, the last of them will not expire until 2015, thirty-two years after the date of the original application.

A longer-acting erythropoietin analogue, darbepoetin (dEPO), also known as novel erythropoiesis-stimulating protein (NESP), was launched by Amgen under the brand name Aranesp in 2001. Relative to rEPO, dEPO has a slightly different amino acid sequence and a greater number of oligosaccharide residues. Aranesp comes in 40mcg and 60mcg 1mL vials, and 100mcg and 200mcg prefilled syringes. It's primary advantage is it can be used only once every two weeks in patients without ESRD (end-stage renal disease).

Outside the U.S. Amgen's patents did not prevail and two other brands of EPO are available: Eprex (J&J) and NeoRecormon. (Roche). Two new long-acting forms may be launched in Europe in 2006: CERA (Roche) and Dynepo (Shire)

EPO is generally injected subcutaneously (under the skin) by the patient, although it may also be given intravenously. Several injections weekly are required for the original forms, but the long-acting forms may require injections only once every two weeks. EPO cannot be used by patients with leukemia and should be used cautiously by patients with uncontrolled high blood pressure. An extremely rare but severe adverse effect of EPO is acquired pure red cell aplasia (PRCA), an auto-immune condition in which the bone marrow loses its ability to produce red blood cells, leaving the patient dependent on blood transfusions. Certain lots of the J&J Eprex product were associated with a higher incidence of this problem. Studies at J&J showed that the PRCA was caused by interaction of EPO protein with a rubber compound in the pre-filled syringe used to distribute the product. Substitution of a teflon-coated syringe plunger eliminated the problem. By far the most common side-effect for any EPO products is fever. Also, use of EPO products can lead to an increased chance of the formation of blood clots (see below). Headache, nausea, vomiting, and delerium are also common side-effects.

These generally subside after 2-3 days. Fever lasting longer than 3 days or rising above 103 degrees Fahrenheit (39.5 °C) should be reported to your physician immediately. Concomminant use of aspirin with EPO products is encouraged to reduce the chance of clotting.

All forms of recombinant erythropoeitin are expensive. A dialysis patient, who can expect to require lifelong EPO treatment, will pay up to $10,000 per year for the drug in the U.S. Cancer chemotherapy patients, who require EPO for shorter periods, pay about $1,000 per month in the U.S. Worldwide revenues for sales of EPO were over USD$10 billion in 2004[1].

Erythropoietin as a blood doping agent

Although pharmaceutical EPO has benefited many thousands of anemic patients, it also has a converse side as a blood doping agent sometimes used by healthy athletes to gain a competitive advantage. By increasing the oxygen-carrying capacity of the blood it increases the aerobic respiratory capacity of the muscles, making it appealing to participants in endurance sports such as cycling and long-distance running. It is considered to be especially valuable in multi-stage bicycle races, where it can offset the decrease in red blood cells that occurs over several weeks of racing.

EPO doping probably became common in Grand Tour cycling after pharmaceutical EPO became available in the late 1980s, but there was at the time no way to prove its use in the absence of physical evidence of EPO possession. In retrospect, the deaths of a dozen or more elite cyclists in the early 1990s from heart failure while sleeping, were grim evidence of its overuse.

Excessive use of pharmaceutical EPO can lead to so many red blood cells that the blood becomes thick enough to strain the heart, especially during sleep when the heart rate is low. Beyond a certain point, the increase in haematocrit is actually detrimental to the oxygen carrying capacity due to negative haemodynamic effects, and increases the likelihood of developing symptoms similar to chronic mountain sickness.

The extent of the doping problem became undeniable after the Festina team scandal in the 1998 Tour de France, in which Willy Voet, a soigneur for the team, was apprehended with a huge cache of doping materials, including EPO. He[2] and others[3] later wrote about the widespread use of drugs in cycling.

In the wake of the Festina affair, the Union Cycliste Internationale (UCI) sought to limit EPO doping by testing riders' red blood cell concentrations as measured by hematocrit(HCT), the proportion by volume of blood cells that are red blood cells. A normal HCT in adult men is 41-50%. Under the UCI rule, any rider with a HCT over 50% was temporarily banned from racing. An independent organization, the World Anti-Doping Agency (WADA), was also created.

The response of EPO-doping athletes has been to monitor their HCT using portable blood centrifugation equipment and engineer their use of pharmaceutical EPO to maintain a HCT of just under 50%. When necessary, blood-thinning infusions are used to reduce HCT to a legal level, ideally 49.9%. Team management, doctors and coaches have in some cases been accused of complicity.

In the 2000 Tour de France, a laboratory test to detect residues of pharmaceutical EPO in urine was introduced for the first time as an anti-doping measure. It was developed by the

French National Laboratory for Doping Detection (LNDD). The test method relies on laboratory methods for distinguishing pharmaceutical EPO from the endogenous EPO normally present in an athlete's urine after strenuous exercise. Because existing brands of pharmaceutical EPO are made in cultured animal cells, they have a different pattern of oligosaccharide residues than the native human form.

Although widely applied, the test is controversial. In 2005, Rutger Beke, a Belgian triathlete successfully challenged his conviction for EPO doping by presenting scientific evidence that the test was unreliable in his case. Several other athletes have since made similar defenses. In the highest profile case to date, Spanish rider Roberto Heras was stripped of what would have been his fourth win of the Vuelta a España in 2005 after a positive urine test for pharmaceutical EPO. He has asserted his innocence and vowed to challenge the conviction based on the handling of his sample and alleged weaknesses in the test method.

If Dynepo becomes available as a pharmaceutical product in 2006 as expected, it may be a boon to doping athletes. It is to be manufactured in cultured human cells and should thus have an authentic pattern of human glycosylation, making it undetectable by the current test method.

Erythropoietin and Jehovah's Witnesses

Jehovah's Witnesses believe that they are to "abstain from blood"; this belief results in the refusal to accept transfusions of blood or blood components.

The use of erythropoietin to increase the number of red blood cells is one suggested alternative to a blood transfusion.

However, the presence of human albumin in the erythropoietin mixture may preclude its use in some Jehovah's Witnesses.

Fluticasone/salmeterol (Advair)

The combination preparation *fluticasone/salmeterol* is a formulation containing fluticasone propionate and salmeterol xinafoate used in the management of asthma and chronic obstructive pulmonary disease (COPD). It is marketed by GlaxoSmithKline under various trade names including *Advair* and *Seretide*.

Formulations

Advair is available in 3 dosage strengths. The smallest dosage is 100/50, the intermediate dosage is 250/50 and the highest dosage is 500/50. The first number in the dosage description is how many micrograms of fluticasone propionate and the second number how many micrograms of salmeterol.

Internationally the fluticasone/salmeterol combination is delivered by a number of devices, including standard aerosol metered dose inhalers (brand name "Evohaler®" in the UK) or dry-powder devices termed "Accuhaler" in the UK and Australia, and "Diskus" in the U.S. These purple disk-shaped containers are about 3.5 inches (8.9 cm) across and about 1 inch thick (2.5 cm). The diskus container holds small pellets of the drug combination, which are crushed on a dose-per-dose basis into a fine powder utilizing an internal mechanism activated by pressing a small lever on the side of the container. The powder is then inhaled directly into the lungs through a mouthpiece. Fluticasone/salmeterol is usually inhaled two times a day.

Fluticasone, a corticosteriod, is the anti-inflammatory component of the combination, while salmeterol treats constriction of the airways. Together, they relieve the symptoms of coughing, wheezing and shortness of breath better than either fluticasone or someterol taken on its own.

Side effects

The common and minor side effects of this combination are those of its individual drugs. For instance, the use of inhaled corticosteroids is associated with oral candidiasis.

Whilst the use of inhaled steroids and long acting beta-adrenoceptor agonist (LABA) are recommended in asthma guidelines for the resulting improved symptom control,[1] concerns have been raised that salmeterol may increase the small risks of asthma deaths and this additional risk is not reduced with the additional use of inhaled steroids.[2] This seems to occur because although LABAs relieve asthma symptoms, they also promote bronchial inflammation and sensitivity without warning.[3]

In a clinical trial, thirteen people died out of a group of 13,176 people taking ADVAIR.

Other side effects include increased blood pressure, change in heart rate, or an irregular heartbeat.

Vasoconstrictor

A *vasoconstrictor*, also *vasopressor* and simply *pressor*, is any substance or that acts to cause vasoconstriction (narrowing of the lumena of blood vessels) and usually results in an increase of the blood pressure. The opposite process, vasodilation, is the opening of blood vessels.

Many vasoconstrictors act on specific receptors, such as vasopressin receptors or adrenoreceptors. Vasoconstrictors are also used clinically to increase blood pressure or to reduce local blood flow. Exposure to moderately high levels of stress also induces vasoconstriction.

Vasoconstriction also occurs in superficial blood vessels of warm-blooded animals when their ambient environment is cold; this process diverts the flow of heated blood to the center of the animal, preventing the loss of heat.

Examples of vasoconstrictors

- Antihistamines
    - Adrenaline

Asymmetric dimethylarginine
ATP

- Cannabis
    - Catecholamines
- Cocaine
- Decongestants
    - Endothelin

Phenylephrine
Pseudoephedrine
Neuropeptide Y
Norepinephrine
Tetrahydrozoline hydrochloride (in eye drops)
Thromboxane

Abortifacients

An *abortifacient* is a substance that induces abortion.

History

The ancient Greek colony of Cyrene at one time had an economy based almost entirely on the production and export of Silphium, a powerful abortifacient in the parsley family. Silphium figured so prominently in the wealth of Cyrene that the plant appeared on the obverse and reverse of coins minted there. Silphium, which was native only to that part of Libya, was overharvested by the Greeks and was effectively driven to extinction.

As the Catholic Church gained control of European society, women who dispensed abortifacient herbs found themselves classified as witches and were often persecuted. [1]

Present time

Herbal abortifacients

Many herbs sold "over the counter" today, including Wild carrot, Black cohosh, Pennyroyal, Nutmeg, and Mugwort, are themselves abortifacients. Typically the labeling will contraindicate use by pregnant women, but will not contain an explanation for this contraindication. There are naturally occurring abortifacients like green Papaya and Common Rue though there does not seem to be any available data on their efficacy.

King's American Dispensatory of 1898 recommended a mixture of brewer's yeast and pennyroyal tea as "a safe and certain abortive"

Pharmaceutical abortifacients

The methods of operation of prescription drugs used as abortifacients are better understood than those of traditional herbal remedies, but they have been controversial since the 1980s. The most prominent of these is Mifepristone (also known as "RU-486" and marketed under the brand name "Mifeprex"), which is used in conjunction with Misoprostol (an anti-ulcer drug marketed under the name "Cytotec"). Mifepristone has been approved for inducing abortions in many Western countries since the late 1990s, while this use of Misoprostol is off-label.

Misoprostol alone is sometimes used for self-induced abortion in Latin American countries where legal abortion is not available, and by some immigrants from these countries in the United States who cannot afford a legal abortion.

Pre-implantation labeling controversy

There is controversy as to whether a woman is pregnant at the time of fertilization, or at the implantation of the blastocyst in the uterine lining. Some agents have a proposed back-

up effect of preventing implantation and thus destroying the blastocyst, although their primary effect is to prevent fertilization. American federal and British laws mark the beginning of pregnancy at implantation; thus, these agents are labeled as contraceptives, rather than abortifacients. They are generally not effective if taken after implantation.[2] Labeling of these agents as abortifacient is most ardently supported by those opposed to abortion, [3] usually due to their belief that human life begins at fertilization. The following agents may prevent implantation of a blastocyst, although, in most cases, they merely prevent fertilization:[4]

- Hormonal contraceptives
    - Combined estrogen & Progesterone:
        - Combined oral contraceptive pill ("The Pill")*
        - Contraceptive patch
        - Contraceptive vaginal ring
        - Lunelle (monthly injection)
    - Progesterone used alone:
        - Progesterone only pill (POP)*
        - Depo Provera (injection every three months)
        - Implants (such as Norplant or Implanon)
        - IntraUterine System ("IUS")
- Intrauterine device ("IUD")*
- Some herbal contraceptives may work primarily by preventing implantation

(*) These methods may also be used as Emergency contraception. POPs are also packaged for use as emergency contraception under the brand name "Plan B".

Quinine

Systematic (IUPAC) name

(2-ethenyl-4-azabicyclo[2.2.2]oct-5-yl)- (6-methoxyquinolin-4-yl)-methanol

Identifiers

CAS number 130-95-0

ATC code M09**AA01** P01**BC01**

PubChem 8549

DrugBank APRD00563

Chemical data

Formula $C_{20}H_{24}N_2O_2$

Mol. weight 324.417 g/mol

Physical data

Melt. point 177 °C (351 °F)

Pharmacokinetic data

Bioavailability **76 to 88%**

Protein binding ~70%

Metabolism Hepatic (mostly CYP3A4 and CYP2C19-mediated)

Half life ~18 hours

Excretion Renal (20%)

Therapeutic considerations

Pregnancy cat. X $_{\text{(U.S.)}}$, D $_{\text{(Au)}}$

Routes Oral

Quinine is a natural white crystalline alkaloid having antipyretic, anti-malarial with analgesic and anti-inflammatory properties and a bitter taste. It is a stereoisomer of quinidine.

Quinine was previously superseded by chloroquine, but is now again the drug of choice for treatment of falciparum malaria because of the rise of chloroquine resistance. Quinine is available with a prescription in the U.S.. Quinine is also used to treat nocturnal leg cramps and arthritis and it has also been used (with limited success) to treat people who had been infected by prions. It was once a popular heroin adulterant.

Mechanism of action

The theorized mechanism of action for quinine and related anti-malarial drugs is that these drugs are toxic to the malaria parasite, specifically by interfering with the parasite's ability to break down and digest hemoglobin, thus starving the parasite and/or causing the build-up of toxic levels of partially degraded hemoglobin in the parasite.

Sources of quinine

Quinine was extracted from the bark of the South American cinchona tree, isolated and named in 1820 by French researchers Pierre Joseph Pelletier and Joseph Caventou. The name was derived from the original Quechua (Native American) word for the cinchona tree bark, "Quina" or "Quina-Quina", which roughly means "bark of bark" or "holly bark". Prior to 1820, the bark was first dried, ground to a fine powder, and then mixed into a liquid (commonly wine) before being drunk.

The large scale use of quinine as a prophylactic started around 1850, although it had been used in un-extracted form by Europeans since at least the early 1600s. Quinine was first used to treat malaria in Rome in 1631. During the 1600s, malaria was endemic to the swamps and marshes surrounding the city of Rome. Over time, malaria was responsible for the death of several Popes, many Cardinals, and countless common citizens of Rome. Most of the priests trained in Rome had seen malaria victims, and were familiar with the shivering brought on by the cold phase of the disease. In addition to its anti-malarial properties, quinine is an effective muscle relaxant, long used by the Quechua Indians of Peru to halt shivering brought on by cold temperatures. The Jesuit priest Agostino Salumbrino, an apothecary by training who lived in Lima, observed the Quechua using the quinine-containing bark of the cinchoa tree for that purpose. While its effect in treating malaria (and hence malaria-induced shivering) was entirely unrelated to its effect in controlling shivering from cold, it was still the correct medicine for malaria. At the first opportunity, he sent a small quantity to Rome to test in treating malaria. In the years that followed, cinchona bark became one of the most valuable commodities shipped from Peru to Europe.

Cinchona trees remain the only practical source of quinine. However, under wartime pressure, research towards its artificial production was undertaken. A formal chemical synthesis was accomplished in 1944 by R.B. Woodward and W.E. Doering, American chemists. Since then, several more efficient total syntheses have been achieved (see review article in Angewandte Chemie, Int. Ed., 2005, 44, p. 854 ff), but none of them can compete in economic terms with isolation of the alkaloid from natural sources.

Dosing

Quinine is an extremely basic compound and is therefore always presented as a salt. Various preparations that exist include the hydrochloride, dihydrochloride, sulphate, bisulphate, and gluconate. This makes quinine dosing very complicated, because each of the different salts has a different weight:

- quinine base 100mg, is equivalent to
- quinine bisulphate 169mg, is equivalent to
- quinine dihydrochloride 122 mg, is equivalent to

- quinine hydrochloride 122 mg, is equivalent to
- quinine sulphate 121 mg, is equivalent to
- quinine gluconate 160mg.

All quinine salts may be given orally or intravenously (IV); quinine gluconate may also be given intramuscularly (IM) or rectally (PR). [1][2] The main problem with the rectal route is that the dose can be expelled before it is completely absorbed, but this can be rectified by giving half dose again.

The IV dose of quinine is 8mg/kg of quinine base every eight hours; the IM dose is 12.8mg/kg of quinine base twice daily; the PR dose is 20mg/kg of quinine base twice daily. Treatment should be given for seven days.

The preparations available in the UK are quinine sulphate (200mg or 300mg tablets) and quinine hydrochloride (300mg/ml for injection). Quinine is not licensed for IM or PR use in the UK. The adult dose in the UK is 600mg quinine dihydrochloride IV or 600mg quinine sulphate PO every eight hours.

In the US, quinine sulphate is available as 324mg tablets; the adult dose is two tablets every eight hours. There is no injectable preparation of quinine licensed in the US: quinidine is used instead;[3][4].

Side effects

It is usual for quinine in therapeutic doses to cause cinchonism; in rare cases, it may even cause death (usually by pulmonary edema). The development of mild cinchonism is not a reason for stopping or interrupting quinine therapy and the patient should be reassured. Blood glucose levels and electrolyte concentrations must be monitored when quinine is given by injection; the patient should also ideally be in cardiac monitoring when the first quinine injection is given (these precautions are often unavailable in developing countries where malaria is most a problem).

Cinchonism is much less common when quinine is given by mouth, however, oral quinine is not well tolerated (quinine is exceedingly bitter and many patients will vomit up quinine tablets): other drugs such as Fansidar® (sulfadoxine with pyrimethamine) or Malarone® (proguanil with atovaquone) are often used when oral therapy is required. Blood glucose, electrolyte and cardiac monitoring are not necessary when quinine is given by mouth.

Quinine can cause paralysis if accidentally injected into a nerve.

Quinine is extremely toxic in overdose and the advice of a poisons specialist should be sought immediately.

Quinine and pregnancy

In very large doses, quinine also acts as an abortifacient; in the U.S., quinine is classed as a Category X teratogen by the Food and Drug Administration, meaning that it can cause birth defects (especially deafness) if taken by a woman during pregnancy. In the UK, the recommendation is that pregnancy is not a contra-indication to quinine therapy for falciparum malaria (which directly contradicts the US recommendation), although it should

be used with caution; the reason for this is that the risks to the pregnancy are small and theoretical, as opposed to the very real risk of death from falciparum malaria.

Quinine and interactions with other diseases

Quinine can cause haemolysis in G6PD deficiency, but again, this risk is small and the physician should not hesitate to use quinine in patients with G6PD deficiency when there is no alternative available. Quinine can also cause drug-induced immune thrombocytopenic purpura (ITP), with quinine being the culprit.

Quinine can cause abnormal heart rhythms and should be avoided if possible in patients with atrial fibrillation, conduction defects or heart block.

Quinine must not be used in patients with haemoglobinuria, myasthenia gravis or optic neuritis, because it worsens these conditions.

Non-medical uses of quinine

Quinine is a flavour component of tonic water and bitter lemon. According to tradition, the bitter taste of anti-malarial quinine tonic led British colonials in India to mix it with gin, thus creating the gin and tonic cocktail, which is still popular today in both India and Great Britain, and in other former British colonies.

In the United States, the Food and Drug Administration limits tonic water quinine to 83 ppm, which is one-half to one-quarter the concentration used in therapeutic tonic.

In France, quinine is an ingredient of an apéritif known as Quinquina.

Quinine is often added to street drugs cocaine or ketamine in order to "cut" the product and make more profit.

Because of its relatively constant and well-known fluorescence quantum yield, quinine is also used in photochemistry as a common fluorescence standard.

In Canada, quinine is an ingredient in the carbonated chinotto beverage called Brio.

In the UK, quinine is an ingredient in the carbonated and caffienated beverage, Irn-Bru.

Gin and tonic

A *gin and tonic*, is a cocktail made with gin and tonic water, usually garnished with a slice of lime and served over ice. The ratio of gin to tonic water varies from equal amounts to one part gin for every three parts tonic.

History

This cocktail was introduced by the British in India. Tonic water contains quinine, which was used to prevent malaria. Because the tonic water consumed to prevent malaria in the 19th century was extremely bitter, gin was added to make it more palatable. Although there is less medical use today for the consumption of tonic water, the gin and tonic remains a popular drink. Tonic water available today contains less quinine and is consequently less bitter (usually sweetened). Because of this connection to warmer climates and its refreshing nature, this cocktail is more popular during the warmer months.

Lore has it that the sheer quantity of limes (for the prevention of scurvy) and quinine (for the aforementioned prevention of malaria), was so unpalatable that the only way to get the members of the British Army to consume the prescribed amount was with the addition of gin. [[1]]

In popular culture

The gin and tonic has gained a central place in cultural and literary life, appearing as a bit part in numerous novels. One such example is in the Hitchhiker's Guide to the Galaxy series, where it is stated that eighty-five percent of the races in the galaxy have each independently developed drinks that are pronounced the same, but spelled differently (such as jynnantonnyx), and which bear no resemblance to one another other than the pronunciation of the name. The reason for this is one of the great mysteries of the universe.

The gin and tonic was the usual drink of Bertie Wooster when he was in need of refreshment or, more often, fortification to help face the many problems that cropped up in his life.

It was the preferred drink of Mrs. Slocombe (played by Mollie Sugden) of Are You Being Served?, as she couldn't bear neat gin.

British singer Nik Kershaw's 1983 hit song I Won't Let the Sun Go Down on Me includes the line "Forty winks in the lobby, make mine a g&t."

In Big Bad Voodoo Daddy's song You & Me & The Bottle Makes Three Tonight (Baby) "a gin and tonic sounds mighty mighty good to me."

In the episode of The Simpsons entitled Flaming Moe's, Moe the bartender looks at a chart of cocktail drinks and says, "Gin and... tonic? Do they mix?"

In the Barenaked Ladies song "Alcohol" it is mentioned in the lyric "A malibu and coke for you, a g&t for me."

The Spiritual Beggars song "Angel of Betrayal" includes the lyrics "Gin and Tonic rules/Blood on the floor/Burn marks from cigarettes/My throat pleads for more".

Oasis' 1994 debut single "Supersonic" features the lyric "I'm feelin' Supersonic, give me gin and tonic."

It was the preferred drink of fictional character John Constantine from the comic series Hellblazer.

It is featured in the Ramones song "Somebody put something in my drink" in the line "Tanqueray and tonic/ my favorite drink/ I don't like anything/ colored pink"

It is referenced in Billy Joel's famous song "Piano Man" in the line "There's an old man sitting next to me/ making love to his tonic and gin"

Reverend Horton Heat have a song named "Gin and Tonic Blues" and the lyrics are just: "I need a Gin'n'Tonic water, baby/Gin'n'Tonic water feelin' better/Give me a Gin'n'Tonic/Gin'n'Tonic/I need it now! (repeat many times)"

Pete Doherty and Carl Barat of The Libertines are both very fond of gin. Carl has written a song called 'Gin And Milk' and Pete has written one called 'Gang Of Gin'[citation needed]. Pete sings about "met two fellas over gin and mixers" in the song "La Belle Et La Bête" and "Well, I'll confess all of my sins after several large gins" in "Music When The Lights Go Out".

Adam Sandler references it in "The Chanukah Song" in the line "Drink your gin and tonic-ah and smoke your marijuani-kah"

Similar Drinks

Sometimes gin is mixed with Sprite, 7up or even ginger ale and garnished with lemon or lime. The sweeter soft drinks are sometimes preferred to tonic water. Although none of these are actually a gin & tonic, they are sometimes called so.

Sometimes apple juice or apple schnapps can be added to a gin and tonic. This is referred to as a GTA or Grand Theft Auto.

Tonic water

Tonic water (or *Indian tonic water*) is a carbonated soft drink flavoured with quinine. The drink gains its name from the medicinal effects of this slightly bitter flavouring.

The quinine was added to the drink as a prophylactic against malaria, since it was originally intended for consumption in tropical areas of India and Africa where that disease is endemic.

Tonic water originally contained only carbonated water and quinine, and it contained a large amount of the latter. However, most tonic water today contains a medically insignificant amount of quinine, and is thus used for its flavor only. It is consequently less bitter, and is also usually sweetened. Some manufacturers also produce diet tonic water.

In the United States, the Food and Drug Administration limits tonic water quinine to 83 ppm (83 mg per litre if calculated by mass), which is one-half to one-quarter the concentration used in therapeutic tonic.

Tonic water is often used as a mixer for alcoholic spirits, especially gin (the mixture commonly known as a gin and tonic).

Tonic water with lemon or lime flavor added is known as bitter lemon or bitter lime, respectively. Such soft drinks are more popular in Europe than in the United States.

Tonic water will glow under ultraviolet light, due to the quinine in it.

Analgesics

An *analgesic* (colloquially known as a *painkiller*) is any member of the diverse group of drugs used to relieve pain (achieve analgesia). This derives from Greek an-, "without", and -algia, "pain". Analgesic drugs act in various ways on the peripheral and central nervous system; they include paracetamol (acetaminophen), the nonsteroidal anti-inflammatory drugs (NSAIDs) such as the salicylates, narcotic drugs such as morphine, synthetic drugs with narcotic properties such as tramadol, and various others. Some other classes of drugs not normally considered analgesics are used to treat neuropathic pain syndromes; these include tricyclic antidepressants and anticonvulsants.

The major classes

Paracetamol and NSAIDs

The exact mechanism of action of paracetamol is uncertain, but it appears to be acting centrally. Aspirin and the NSAIDs inhibit cyclooxygenase, leading to a decrease in prostaglandin production; this improves pain and also inflammation (in contrast to paracetamol and the opioids).

Paracetamol has few side effects, but dosing is limited by possible hepatotoxicity (potential for liver damage). NSAIDs may predispose to peptic ulcers, renal failure, allergic reactions, and hearing loss. They may also increase the risk of hemorrhage by affecting platelet function. The use of certain NSAIDs in children under 16 suffering from viral illness may contribute to Reye's syndrome.

COX-2 inhibitors

These drugs have been derived from NSAIDs. The cyclooxygenase enzyme inhibited by NSAIDs was discovered to have at least 2 different versions: COX1 and COX2. Research suggested that most of the adverse effects of NSAIDs were mediated by blocking the COX1 (constitutive) enzyme, with the analgesic effects being mediated by the COX2 (inducible) enzyme. The COX2 inhibitors were thus developed to inhibit only the COX2 enzyme (traditional NSAIDs block both versions in general). These drugs (such as rofecoxib and celecoxib) are equally effective analgesics when compared with NSAIDs, but cause less gastrointestinal hemorrhage in particular. However post-launch data indicated increased risk of cardiac and cerebrovascular events with these drugs, and rofecoxib was subsequently withdrawn from the market. The role for this class of drug is currently hotly debated.

Opiates and morphinomimetics

Morphine, the archetypal opioid, and various other substances (e.g. pethidine, oxycodone, hydrocodone, diamorphine) all exert a similar influence on the cerebral opioid receptor system. Tramadol and buprenorphine are thought to be partial agonists of the

opioid receptors. Dosing of all opioids may be limited by opioid toxicity (confusion, myoclonic jerks and pinpoint pupils), but there is no dose ceiling in patients who tolerate this.

Opioids, while very effective analgesics, may have some unpleasant side-effects. Up to 1 in 3 patients starting morphine may experience nausea and vomiting (generally relieved by a short course of antiemetics). Pruritus (itching) may require switching to a different opioid. Constipation occurs in almost all patients on opioids, and laxatives (lactulose, macrogol-containing or co-danthramer) are typically co-prescribed.

When used appropriately, opioids and similar narcotic analgesics are safe and effective, carrying relatively little risk of addiction. Occasionally, gradual tapering of the dose is required to avoid withdrawal symptoms.

Specific agents

In patients with chronic or neuropathic pain, various other substances may have analgesic properties. Tricyclic antidepressants, especially amitriptyline, have been shown to improve pain in what appears to be a central manner. The exact mechanism of carbamazepine, gabapentin and pregabalin is similarly unclear, but these anticonvulsants are used to treat neuropathic pain with modest success.

Specific forms and uses

Combinations

Analgesics are frequently used in combination, such as the paracetamol and codeine preparations found in many non-prescription pain relievers. They can also be found in combination with vasoconstrictor drugs such as pseudoephedrine for sinus-related preparations, or with antihistamine drugs for allergy sufferers.

The use of paracetamol concurrently with opiates has been shown to have beneficial synergistic effects and it is generally recommended that they are prescribed together.

Topical or systemic

Topical analgesia is generally recommended to avoid systemic side-effects. Painful joints, for example, may be treated with an ibuprofen- or diclofenac-containing gel; capsaicin also is used topically. Lidocaine and steroids may be injected into painful joints for longer-term pain relief. Lidocaine is also used for painful mouth sores and to numb areas for dental work and minor medical procedures.

Psychotropic agents

Tetrahydrocannabinol and some other cannabinoids, either from the Cannabis sativa plant or synthetic, have analgesic properties, although the use of cannabis derivatives is illegal in many countries. Other psychotropic analgesic agents include ketamine (an NMDA

receptor antagonist), clonidine and other ±2-adrenoreceptor agonists, and mexiletine and other local anaesthetic analogues.

Addiction

In the United States in recent years, however, there has been a wave of new addictions to prescription narcotics such as oxycodone (OxyContin) and hydrocodone (Vicodin, Lortab etc.) when available in pure formulations as opposed to combined with other medications (as in Percocet which contains both oxycodone and acetaminophen/paracetamol).

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs, usually abbreviated to *NSAID*s, are drugs with analgesic, antipyretic and anti-inflammatory effects - they reduce pain, fever and inflammation. The term "non-steroidal" is used to distinguish these drugs from steroids, which (amongst a broad range of other effects) have a similar eicosanoid-depressing, anti-inflammatory action. NSAIDS are unusual in that they are non-narcotic. NSAIDs are sometimes also referred to as *non-steroidal anti-inflammatory agents/analgesics* (*NSAIAs*). The most prominent members of this group of drugs are aspirin and ibuprofen. Paracetamol (acetaminophen) has negligible anti-inflammatory activity, and is strictly speaking not an NSAID.

Beginning in 1829, with the isolation of salicylic acid from the folk remedy willow bark, NSAIDs have become an important part of the pharmaceutical treatment of pain (at low doses) and inflammation (at higher doses). Part of the popularity of NSAIDs is that, unlike opioids, they do not produce sedation or respiratory depression and have a very low addiction rate. NSAIDs, however, are not without their own problems (see below). Certain NSAIDs, including ibuprofen and aspirin, have become accepted as relatively safe and are available over-the-counter without prescription.

Mode of action

Most NSAIDs act as non-selective inhibitors of the enzyme cyclooxygenase, inhibiting both the cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2) isoenzymes. Cyclooxygenase catalyses the formation of prostaglandins and thromboxane from arachidonic acid (itself derived from the cellular phospholipid bilayer by phospholipase A2). Prostaglandins act (among other things) as messenger molecules in the process of

inflammation. This mechanism of action was elucidated by John Vane, who later received a Nobel Prize for his work.

Examples

NSAIDs can be broadly classified based on their chemical structure. NSAIDs within a group will tend to have similar characteristics and tolerability. There is little difference in clinical efficacy between the NSAIDs when used at equivalent doses. Rather, differences between compounds tended to be with regards to dosing regimens (related to the compound's elimination half-life), route of administration, and tolerability profile. Some more common examples are given below.

Paracetamol (acetaminophen), owing to its inhibitory action on cyclooxygenase, is sometimes grouped together with the NSAIDs. Paracetamol, however, does not have any significant anti-inflammatory properties and is not a true NSAID. Though it has not been clearly elucidated, it is suspected that this lack of anti-inflammatory action may be due to the paracetamol inhibiting cyclooxygenase predominantly in the central nervous system. There is also some speculation that paracetamol acts through the inhibition of the recently discovered COX-3 isoform (see below).

Salicylates

- Aspirin
  - Amoxiprin
  Benorilate
  Choline magnesium salicylate
  Diflunisal
  Faislamine

- Nimesulide

Others

- Licofelone
Omega-3 Fatty Acids

Uses

NSAIDs are usually indicated for the treatment of acute or chronic conditions where pain and inflammation are present. Research continues into their potential for prevention of colorectal cancer, and treatment of other conditions, such as cancer and cardiovascular disease.

NSAIDs are generally indicated for the symptomatic relief of the following conditions: (Rossi, 2006)

- Rheumatoid arthritis
Osteoarthritis
Inflammatory arthropathies (e.g. ankylosing spondylitis, psoriatic arthritis, Reiter's syndrome)
Acute gout
Dysmenorrhoea
Metastatic bone pain
Headache and migraine
Postoperative pain
Mild-to-moderate pain due to inflammation and tissue injury
Pyrexia
Renal colic

Aspirin, the only NSAID able to irreversibly inhibit COX-1, is also indicated for inhibition of platelet aggregation; an indication useful in the management of arterial thrombosis and prevention of adverse cardiovascular events.

In 2001, NSAIDs accounted for 70,000,000 prescriptions and 30 billion over-the-counter doses sold annually in the United States. (Green, 2001). With the aging of the Baby Boomer generation and the associated rise in the incidence of osteoarthritis and other such conditions for which NSAIDs are indicated, the use of NSAIDs may increase further still.

Pharmacokinetics

Most NSAIDs are weak acids, with a pKa of 3-5. They are absorbed well from the stomach and intestinal mucosa. They are highly protein-bound in plasma (typically >95%), usually to albumin, so that their volume of distribution typically approximates to plasma volume. Most NSAIDs are metabolised in the liver by oxidation and conjugation to inactive metabolites which are typically excreted in the urine, although some drugs are partially excreted in bile.

Metabolism may be abnormal in certain disease states, and accumulation may occur even with normal dosage.

Ibuprofen and diclofenac have short half-lives (2-3 hours). Some NSAIDs (typically oxicams) have very long half-lives (e.g. 20-60 hours).

Adverse effects

The widespread use of NSAIDs has meant that the adverse effects of these relatively safe drugs have become increasingly prevalent. The two main adverse drug reactions (ADRs), associated with NSAIDs relate to gastrointestinal (GI) effects and renal effects of the agents.

These effects are dose-dependent, and in many cases severe enough to pose the risk of ulcer perforation, upper gastrointestinal bleeding, and death, limiting the use of NSAID therapy. An estimated 10-20% of NSAID patients experience dyspe gastrointestinal (GI) effects and renal epsia, and NSAID-associated upper gastrointestinal adverse events are estimated to result in 103,000 hospitalizations and 16,500 deaths per year in the United States, and represent 43% of drug-related emergency visits. Many of these events are avoidable; a review of physician visits and prescriptions estimated that unnecessary prescriptions for NSAIDs were written in 42% of visits. (Green, 2001)

Cardiovascular risk

A recent meta-analysis of all trials comparing non-steroidal anti-inflammatory drugs found a 80% increase in the risk of myocardial infarction with both newer Cox-2 antagonists and high dose traditional anti-inflammatories compared with placebo, with the important exception of naproxen, which was not associated with an increased cardiovascular risk (Kearney et al, BMJ 2006;332:1302-1308).

Gastrointestinal ADRs

The main ADRs associated with use of NSAIDs relate to direct and indirect irritation of the gastrointestinal tract (GIT). NSAIDs cause a dual insult on the GIT - the acidic molecules directly irritate the gastric mucosa; and inhibition of COX-1 reduces the levels of protective prostaglandins.

Common gastrointestinal ADRs include: (Rossi, 2006)

- Nausea
- Dyspepsia
- Gastric ulceration/bleeding
- Diarrhea

Risk of ulceration increases with duration of therapy, and with higher doses. In attempting to minimise GI ADRs, it is prudent to use the lowest effective dose for the shortest period of time, a practice which studies show is not often followed.

There are also some differences in the propensity of individual agents to cause gastrointestinal ADRs. Indomethacin, ketoprofen and piroxicam appear to have the highest

prevalence of gastric ADRs, while ibuprofen (lower doses) and diclofenac appear to have lower rates. (Rossi, 2006)

Certain NSAIDs, such as aspirin, have been marketed in enteric-coated formulations which are claimed to reduce the incidence of gastrointestinal ADRs. Similarly, there is a belief that rectal formulations may reduce gastrointestinal ADRs. However, in consideration of the mechanism of such ADRs and indeed in clinical practice, these formulations have not been shown to have a reduced risk of GI ulceration. (Rossi, 2006)

Commonly, gastrointestinal adverse effects can be reduced through suppressing acid production, by concomitant use of a proton pump inhibitor, e.g. omeprazole; or the prostaglandin analogue misoprostol. Misoprostol is itself associated with a high incidence of gastrointestinal ADRs (diarrhoea). While these techniques may be effective, they prove to be expensive for maintenance therapy.

Renal ADRs

NSAIDs are also associated with a relatively high incidence of renal ADRs. The mechanism of these renal ADRs is probably due to changes in renal haemodynamics (bloodflow), ordinarily mediated by prostaglandins, which are affected by NSAIDs. Horses are particularly prone to these adverse affects compared to other domestic animal species.

Common ADRs associated with altered renal function include: (Rossi, 2006)

- Salt and fluid retention
- Hypertension

These agents may also cause renal impairment, especially in combination with other nephrotoxic agents. Renal failure is especially a risk if the patient is also concomitantly taking an ACE inhibitor and a diuretic - the so-called "triple whammy" effect. (Thomas, 2000)

In rarer instances NSAIDs may also cause more severe renal conditions: (Rossi, 2006)

- Interstitial nephritis

Nephrotic syndrome
Acute renal failure
Acute tubular necrosis

Photosensitivity

Photosensitivity is a commonly overlooked adverse effect of many of the NSAIDs. (Moore, 2002) It is somewhat ironic that these anti-inflammatory agents may themselves produce inflammation in combination with exposure to sunlight. The 2-arylpropionic acids have proven to be the most likely to produce photosensitivity reactions, but other NSAIDs have also been implicated including piroxicam, diclofenac and benzydamine.

Benoxaprofen, since withdrawn due to its hepatotoxicity, was the most photoactive NSAID observed. The mechanism of photosensitivity, responsible for the high photoactivity of the 2-arylpropionic acids, is the ready decarboxylation of the carboxylic acid moiety. The specific absorbance characteristics of the different chromophoric 2-aryl substituents, affects the decarboxylation mechanism. While ibuprofen is somewhat of an exception, having weak absorption, it has been reported to be a weak photosensitising agent.

During pregnancy

NSAIDs are not recommended during pregnancy, particularly during the third trimester. While NSAIDs as a class are not direct teratogens, they may cause premature closure of the fetal ductus arteriosus and renal ADRs in the fetus. Additionally, they are linked with premature birth (Ostensen & Skomsvoll, 2004). Aspirin, however, is used together with heparin in pregnant women with antiphospholipid antibodies (Cervera & Balasch, 2004).

In contrast, paracetamol (acetaminophen) is regarded as being safe and well-tolerated during pregnancy (Graham et al., 2005). Doses should be taken as prescribed, due to risk of hepatotoxicity with overdoses (Wilkes et al, 2005).

Other ADRs

Common ADRs, other than listed above, include: raised liver enzymes, headache, dizziness (Rossi, 2006).

Uncommon ADRs include: heart failure, hyperkalaemia, confusion, bronchospasm, rash (Rossi, 2006). Ibuprofen may also rarely cause irritable bowel syndrome symptoms.

Most NSAIDs penetrate poorly into the central nervous system (CNS). However, the COX enzymes are expressed constitutively in some areas of the CNS, meaning that even limited penetration may cause adverse effects such as somnolence and dizziness.

Chirality

Most NSAIDs are chiral molecules (diclofenac is a notable exception). However, the majority are prepared in a racemic mixture. Typically, only a single enantiomer is pharmacologically active. For some drugs, (typically profens) an isomerase enzyme exists in vivo which converts the inactive enantiomer into the active form, although its activity varies widely in individuals. This phenomenon is likely to be responsible for the poor correlation between NSAID efficacy and plasma concentration observed in older studies, when specific analysis of the active enantiomer was not performed.

Ibuprofen and ketoprofen are now available in single, active enantiomer preparations (*dexibuprofen* and *dexketoprofen*), which purport to offer quicker onset and an improved side-effect profile. Naproxen has always been marketed as the single active enantiomer.

Newer NSAIDs: selective COX inhibitors

COX-2 inhibitors

The discovery of COX-2 in 1991 by Daniel L. Simmons at Brigham Young University raised the hope of developing an effective NSAID without the gastric problems characteristic of these agents. It was thought that selective inhibition of COX-2 would result in anti-inflammatory action without disrupting gastroprotective prostaglandins.

COX-1 is a constitutively expressed enzyme with a "house-keeping" role in regulating many normal physiological processes. One of these is in the stomach lining, where

prostaglandins serve a protective role, preventing the stomach mucosa from being eroded by its own acid. When non-selective COX-1/COX-2 inhibitors (such as aspirin, ibuprofen, and naproxen) lower stomach prostaglandin levels, these protective effects are lost and ulcers of the stomach or duodenum and potentially internal bleeding can result. COX-2 is an enzyme facultatively expressed in inflammation, and it is inhibition of COX-2 that produces the desirable effects of NSAIDs.

The relatively selective COX-2 inhibiting oxicam, meloxicam, was the first step towards developing a true COX-2 selective inhibitor. Coxibs, the newest class of NSAIDs, can be considered as true COX-2 selective inhibitors, and include celecoxib, rofecoxib, valdecoxib, parecoxib and etoricoxib.

Controversies with COX-2 inhibitors

While it was hoped that this COX-2 selectivity would reduce gastrointestinal adverse drug reactions (ADRs), there is little conclusive evidence that this is true. The original study touted by Searle (now part of Pfizer), showing a reduced rate of ADRs for celecoxib, was later revealed to be based on preliminary data - the final data showed no significant difference in ADRs when compared with diclofenac.

Rofecoxib however, which has since been withdrawn, had been shown to produce significantly fewer gastrointestinal ADRs compared to naproxen. (Bombardier et al, 2000). This study, the VIGOR trial, raised the issue of the cardiovascular safety of the coxibs - a statistically insignificant increase in the incidence of myocardial infarctions was observed in patients on rofecoxib. Further data, from the APPROVe trial, showed a relative risk of cardiovascular events of 1.97 versus placebo - a result which resulted in the worldwide withdrawal of rofecoxib in October 2004.

COX-3 inhibitors

Simmons also co-discovered COX-3 in 2002 and analyzed this new isozyme's relation to paracetamol (acetaminophen), arguably the most widely used analgesic drug in the world. (Chandrasekharan et al, 2002). The authors postulated that inhibition of COX-3 could represent a primary central mechanism by which these drugs decrease pain and possibly fever.

The clinical ramifications and knowledge of COX isozymes are rapidly expanding and may offer significant hope for future treatments of pain, inflammation, and fever.

NSAID nephropathy

- NSAID or Non-steroidal anti-inflammatory drug, are drugs with analgesic, antipyretic and anti-inflammatory effects - they reduce pain, fever and inflammation. The term "non-steroidal" is used to distinguish these drugs from steroids which have simmiliar effects.
- Nephropathy or nephrosis refers to damage to or disease of the kidney. Therefore *NSAID Nephropathy* is damage to the kidney as a result of taking NSAID drugs.

Symptoms

- Acute renal failure secondary to renal hemodynamic changes Interstitial nephritis with or without proteinuria/nephrotic syndrome Hypertension

Epidemiology

Epidemiology is the scientific study of factors affecting the health and illness of individuals and populations

- Very low, 1% to 3% of patient exposed experience one of the previously mentioned
- Delayed onset from initial use of NSAID
- Described with use in all types of NSAIDs

The number of people taking NSAIDs is very high, offsetting low rate per user to high rate per population.

Pathophysiology

Pathophysiology is the study of the disturbance of normal mechanical, physical, and biochemical functions that a disease causes, or that which causes the disease

Inhibition of renal prostaglandin synthesis interferes with renal hemodynamics.

PGI2, PGE2 are responsible for:

- vasodilation in the arterioles and glomeruli decreased Na transport and natriuresis in the distal tubules Interferes with ADH action in the distal tubules

TXA2 shown to vasoconstrict glomeruli

Clinical features: NSAID-Induced hemodynamic deterioration of Renal Function

- Prostoglandin Inhibtion leads to further renal vasoconstriction
Especially in setting of already vasocontricted states such as CHF, nephrotic syndrome, cirrhosis, volume depletion, CRI
30% of patient with CRI on NSAIDS develop this syndrome
Elderly also at increased risk mostly secondary to pharmacokinetics
Fully reversible if caught early
Rarely the sole cause of ESRD

Clinical Features: NSAID Associated Tubulointerstial nephritis

- Heavy Proteinuria/Nephrotic syndrome – 83%
Eosinophilia and Eosinophiluria uncommon – 19%
Focal tubulointerstitial infiltrates on biopsy
Some + immunofluorescence for IgG, IgA, IgM and C3 in interstitial membranes
Non-oliguric course typical
Variable delayed onset
May take weeks to many months to resolve, after stopping NSAID

Clinical Features: NSAID associated Hypertension

- Usually only a modest increase in BP – an average increase of 6-8mmHg pf MAP in patient on NSAIDs
- NSAIDs mitigate effects of B-blockers and diuretics
- CCB less susceptible to effects of NSAIDs
- Elderly, Blacks, low renin hypertension most susceptible

Clinical Oddballs

- Minimal change disease/Nephrotic syndrome
- Hyperkalemia – NSAIDs anecdotally used to treat Barter's

Treatment

- Withdraw NSAIDs
- Avoid Nephrotoxic meds
- +/- Steroids with NSAID associated tubulointerstitial nephritis

Systematic (IUPAC) name 2-(acetyloxy)benzoic acid

Identifiers
CAS number 50-78-2

ATC code **A01**AD05 **B01**AC06**, N02**BA01

PubChem 2244

DrugBank APRD00264

Chemical data

Formula C***9***H***8***O***4*** C6H4(OCOCH3)COOH

Mol. weight 180.16 g/mol

Synonyms 2-acetyloxybenzoic acid, 2-acetoxybenzoic acid, acetylsalicylate, acetylsalicylic acid, O-acetylsalicylic acid

Physical data

Density 1.40 g/cm^3

Melt. point 138-140 °C (-82 °F)

Boiling point 140 °C (284 °F)

Solubility in water 4.6 mg/mL (20 °C)

Pharmacokinetic data

Bioavailability rapid & complete

Protein binding 99.6%

Metabolism hepatic

Half life 300-650mg dose 3.1-3.2hrs, 1 g dose 5 hours, 2 g dose 9 hours

Excretion renal

Therapeutic considerations

Pregnancy cat. C(AU) C(US)

Legal status GSL(UK) OTC(US)

Routes oral

Aspirin or *acetylsalicylic acid* (acetosal) is a drug in the family of salicylates, often used as an analgesic (against minor pains and aches), antipyretic (against fever), and anti-inflammatory. It has also an antiplatelet ("blood-thinning") effect and is used in long-term low-doses to prevent heart attacks and cancer.

Low-dose long-term aspirin irreversibly blocks the formation of thromboxane A2 in platelets, producing an inhibitory effect on platelet aggregation, and this blood-thinning property makes it useful for reducing the incidence of heart attacks. Aspirin produced for this purpose often comes in 75 or 81 mg dispersible tablets and is sometimes called "Junior aspirin" or "Baby aspirin." High doses of aspirin are also given immediately after an acute heart attack. These doses may also inhibit the synthesis of prothrombin and may therefore produce a second and different anticoagulant effect.

Several hundred fatal overdoses of aspirin occur annually, but the vast majority of its uses are beneficial. Its primary undesirable side effects, especially in higher doses, are gastrointestinal distress (including ulcers and stomach bleeding) and tinnitus. Another side effect, due to its anticoagulant properties, is increased bleeding in menstruating women.

Because there appears to be a connection between aspirin and Reye's syndrome, aspirin is no longer used to control flu-like symptoms or the symptoms of chickenpox in minors.[1]

Aspirin was the first discovered member of the class of drugs known as non-steroidal anti-inflammatory drugs (NSAIDs), not all of which are salicylates, though they all have similar effects and a similar action mechanism.

Aspirin as genericized trademark

The brand name Aspirin was coined by the Bayer company of Germany. In some countries the name is used as a generic term for the drug rather than the manufacturer's trademark. In countries in which Aspirin remains a trademark, the initialism *ASA* (for acetylsalicylic acid) is used as a generic term (*ASS* in German-language countries, for Acetylsalicylsäure; *AAS* in Spanish- and Portuguese-language countries, for ácido acetilsalicílico and in French-language countries, for acide acétylsalicylique).

The name "aspirin" is composed of a- (from the acetyl group) -spir- (from the plant genus Spiraea) and -in (a common ending for drugs at the time). It has also been stated that the name originated by another means. "As" referring to AcetylSalicylic and "pir" in reference to one of the scientists who was able to isolate it in crystalline form, Raffaele Piria. Finally "in" due to the same reasons as stated above.

On March 6, 1899 Bayer registered it as a trademark. However, the German company lost the right to use the trademark in many countries as the Allies seized and resold its foreign assets after World War I. The right to use "Aspirin" in the United States (along with all other Bayer trademarks) was purchased from the U.S. government by Sterling Drug in 1918. Even before the patent for the drug expired in 1917, Bayer had been unable to stop competitors from copying the formula and using the name elsewhere, and so, with a flooded market, the public was unable to recognize "Aspirin" as coming from only one manufacturer. Sterling was subsequently unable to prevent "Aspirin" from being ruled a genericized trademark in a U.S. federal court in 1921. Sterling was ultimately acquired by Bayer in 1994, but this did not restore the U.S. trademark. Other countries (such as Canada and many countries in Europe) still consider "Aspirin" a protected trademark.

Discovery

Hippocrates, a Greek physician, wrote in the 5th century BC about a bitter powder extracted from willow bark that could ease aches and pains and reduce fevers. This remedy is also mentioned in texts from ancient Sumer, Lebanon and Assyria. Native Americans have used the bark and the leaves of the willow for medicinal purpose for centuries. The medicinal part of the plant is the inner bark and was used as a pain reliever for a variety of ailments. Cherokees used an infusion of the bark for fever, rheumatic pains, insomnia, dysentery, and sore throats. The Reverend Edward Stone, a vicar from Chipping Norton, Oxfordshire England, noted in 1763 that the bark of the willow was effective in reducing a fever.[2]

The active extract of the bark, called salicin, after the Latin name for the White willow (Salix alba), was isolated to its crystalline form in 1828 by Henri Leroux, a French

pharmacist, and Raffaele Piria, an Italian chemist. Piria was able to convert the substance into a sugar and a second component, which on oxidation becomes salicylic acid.

Salicylic acid was also isolated from meadowsweet (Filipendula ulmaria, formerly classified as Spiraea ulmaria) by German researchers in 1839. While their extract was somewhat effective, it also caused digestive problems such as gastric irritation and bleeding, and diarrhea, and even death when consumed in high doses. In 1853, a French chemist named Charles Frederic Gerhardt neutralized salicylic acid by buffering it with sodium (sodium salicylate) and acetyl chloride, creating acetosalicylic anhydride. Gerhardt's product worked, but he had no desire to market it and abandoned his discovery. In 1897, researcher Arthur Eichengrun and Felix Hoffmann, a research assistant at Friedrich Bayer & Co. in Germany, derivatized one of the hydroxyl functional groups in salicylic acid with an acetyl group (forming acetylsalicylic acid, an acetyl ester). This thereby greatly reduced the negative effects caused by the free phenolic group of salicylic acid. When in the body, the ester (aspirin) is hydrolyzed to free the active drug. This was the first synthetic drug, not a copy of something that existed in nature, and the start of the pharmaceuticals industry.

Hoffmann made some of the formula and gave it to his father, who was suffering from the pain of arthritis and could not stand the side effects of salicylic acid. With good results, he then convinced Bayer to market the new wonder drug. 'Aspirin' was patented on March 6, 1899. It was marketed alongside another of Hoffmann's products, an acetylated synthetic of morphine called 'Heroin' that he invented 11 days after Aspirin. Heroin was initially the more successful of the two painkillers and it was common belief that it was healthier than Aspirin. But, as Heroin's shortcoming of addictiveness became more obvious, Aspirin stepped to the forefront. Aspirin was originally sold as a powder (still the preferred form in many European countries) and was an instant success; in 1915, Bayer introduced Aspirin tablets.

Several claims to invention of acetylsalicylic acid have arisen. Acetylsalicylic acid was already being manufactured by the Chemische Fabrik von Heyden Company in 1897, although without a brand name. Arthur Eichengrün claimed in 1949 that he planned and directed the synthesis of aspirin while Hoffmann's role was restricted to the initial lab synthesis using Eichengrün's process. In 1999, Walter Sneader of the Department of Pharmaceutical Sciences at the University of Strathclyde in Glasgow reexamined the case and agreed with Eichengrün's account. Bayer continues to recognize Felix Hoffmann as aspirin's official inventor. Despite its argued origin, Bayer's marketing was responsible for bringing it to the world.

It was not until the 1970s that the mechanism of action of aspirin and similar drugs called NSAIDs was elucidated (see below).

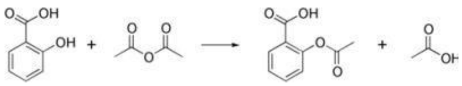
Synthesis of aspirin

Aspirin is commercially synthesized using a two-step process. First, phenol (generally extracted from coal tar) is treated with a sodium base generating sodium phenoxide, which is then reacted with carbon dioxide under high temperature and pressure to yield salicylate, which is acidified, yielding salicylic acid. This process is known as the Kolbe-Schmitt reaction.

Salicylic acid is then acetylated using acetic anhydride, yielding aspirin and acetic acid as a byproduct. It is a common experiment performed in organic chemistry labs, and generally

tends to produce low yields due to the relative difficulty of its extraction from an aqueous state. The trick to getting the reaction to work is to acidify with phosphoric acid and heat the reagents under reflux with a boiling water bath for between 40 to 60 minutes.

The original synthesis of aspirin from salicylic acid involved acetylation with acetyl chloride. Unfortunately, the byproduct from this is hydrochloric acid, which is corrosive and environmentally hazardous. As describe above, it was then later found that acetic anhydride was a better acylating agent, with the byproduct acetic acid formed, which does not have the unwanted properties of hydrochloric acid and can also be recycled.



Formulations containing high concentrations of aspirin often smell of vinegar. This is because aspirin can undergo autocatalytic degradation to salicylic acid in moist conditions, yielding salicylic acid and acetic acid.

Mechanism of action

In 1971, the British pharmacologist, John Robert Vane, who was then employed by the Royal College of Surgeons in London, showed that aspirin had suppressed the production of prostaglandins and thromboxanes. For this piece of research he was awarded both a Nobel Prize in Physiology or Medicine in 1982 and a knighthood.

Aspirin's ability to suppress the production of prostaglandins and thromboxanes is due to its non-competitive (irreversible) inhibition of the cyclooxygenase (COX) enzyme. Cyclooxygenase is required for prostaglandin and thromboxane synthesis. Aspirin acts as an acetylating agent where an acetyl group is covalently attached to a serine residue in the active site of the COX enzyme. This makes aspirin different from other NSAIDS (such as diclofenac and ibuprofen), which are reversible inhibitors.

Prostaglandins are local hormones (paracrine) produced in the body and have diverse effects in the body, including but not limited to transmission of pain information to the brain, modulation of the hypothalamic thermostat, and inflammation. Thromboxanes are responsible for the aggregation of platelets that form blood clots. Heart attacks are primarily caused by blood clots, and their reduction with the introduction of small amounts of aspirin has been seen to be an effective medical intervention. The side-effect of this is that the ability of the blood in general to clot is reduced, and excessive bleeding may result from the use of aspirin.

More recent work has shown that there are at least two different types of cyclooxygenase: COX-1 and COX-2. Aspirin inhibits both of them. Newer NSAID drugs called COX-2 selective inhibitors have been developed that inhibit only COX-2, with the hope for reduction of gastrointestinal side-effects.

However, several of the new COX-2 selective inhibitors have been recently withdrawn, after evidence emerged that COX-2 inhibitors increase the risk of heart attack. It is proposed that endothelial cells lining the arteries in the body express COX-2, and, by selectively inhibiting COX-2, prostaglandins (specifically PGF2) are downregulated with respect to thromboxane levels, as COX-1 in platelets is unaffected. Thus, the protective anti-coagulative

effect of PGF2 is decreased, increasing the risk of thrombus and associated heart attacks and other circulatory problems. Since platelets have no DNA, they are unable to synthesize new COX once aspirin has irreversibly inhibited the enzyme, rendering them "useless": an important difference with reversible inhibitors.

Furthermore, aspirin has 2 additional modes of actions, contributing to its strong analgesic, antipyretic and anti-inflammatory properties:

- It uncouples oxidative phosphorylation in cartilaginous (and hepatic) mitochondria.
- It induces the formation of NO-radicals in the body that enable the white blood cells (leukocytes) to fight infections more effectively. This has been found recently by Dr. Derek W. Gilroy, winning Bayer's International Aspirin Award 2005.

More recent data suggest that salicylic acid and its derivatives will modulate NFkB signaling. NFkB is a transcription factor complex that plays a central role in many biological processes, including inflammation.

Indications

Aspirin, as with many older drugs, has proven to be useful in many conditions. Despite its well-known toxicity it is widely used, since physicians are familiar with its properties. Indications for its use include:

- Fever

Pain (especially useful for some forms of arthritis, osteoid osteoma, and chronic pain)
Migraine
Rheumatic fever (drug of choice)
Kawasaki's disease (along with IVIG)
Pericarditis

- Coronary artery disease
  - Acute myocardial infarction[3]

In addition, aspirin is recommended (low dose, 75-81 mg daily) for the prevention of:

- Myocardial infarction - in patients with either documented coronary artery disease or at elevated risk of cardiovascular disease

Stroke - as secondary prevention (i.e. to prevent recurrence)

In the UK, aspirin can be obtained without a prescription.

Dosage

For adults doses of 300 to 1000 mg are generally taken four times a day for fever or arthritis, with a maximum dose of 8000 mg a day.[4] The correct dose of aspirin depends on the disease process that is being treated. For instance, for the treatment of rheumatic fever, doses near the maximal daily dose have been used historically. For the prevention of myocardial infarction in someone with documented or suspected coronary artery disease, doses as low as 75 mg daily (or possibly even lower) are sufficient.

For those under 12 years of age, the dose previously varied with the age, but aspirin is no longer routinely used in children due to the association with Reye's syndrome; paracetamol or other NSAIDs, such as Ibuprofen, now being used instead. Kawasaki disease remains one of the few indications for aspirin use in children with aspirin initially started at 7.5-12.5 mg/kg body weight taken four times a day for up to two weeks and then continued at 5 mg/kg once daily for a further six to eight weeks.[5]

Toxicity of low-dose aspirin

A recent review states: "....low-dose aspirin increases the risk of major bleeding 2-fold compared with placebo. However, the annual incidence of major bleeding due to low-dose aspirin is modest—only 1.3 patients per thousand higher than what is observed with placebo treatment. Treatment of approximately 800 patients with low-dose aspirin annually for cardiovascular prophylaxis will result in only 1 additional major bleeding episode." Further, "...the cost to prevent one major GI bleeding episode from aspirin in 1 year by substituting clopidogrel therapy would be $1,216,180..."[6]

Contraindications and warnings

- Aspirin should be avoided by those known to be allergic to aspirin, ibuprofen or naproxen.
- Caution should be exercised in those with asthma or NSAID-precipitated bronchospasm.
- It is generally recommended that one seek medical help if symptoms do not improve after a few days of therapy.
- Caution should be taken in patients with kidney disease, peptic ulcers, mild diabetes, gout or gastritis; manufacturers recommend talking to one's doctor before using this medicine.
- Taking aspirin with alcohol increases the chance of gastrointestinal hemorrhage (stomach bleeding).
- Children, including teenagers, are discouraged from using aspirin in cold or flu symptoms as this has been linked with Reye's syndrome.[1]
- Patients with hemophilia or other bleeding tendencies should not take salicylates.
- Some sources recommend that patients with hyperthyroidism avoid aspirin because it elevates T4 levels.
- Pets - aspirin may be used in cats, but only under a veterinarian's strict supervision, as aspirin has a biological half-life of 3 days in cats (cats have trouble breaking down aspirin). Dogs may also use aspirin under a vet's strict supervision, though dogs are more susceptible to aspirin-caused GI bleeds than humans. Aspirin is generally not recommended for pets, though, as there are much safer alternatives for pain relief, and aspirin interacts with several other drugs including cortisones, digoxin, some antibiotics, phenobarbital and furosemide (Lasix)

Common side-effects

- Gastrointestinal complaints (stomach upset, dyspepsia, heartburn, small blood loss). To help avoid these problems, it is recommended that aspirin be taken at or after meals. Undetected blood loss may lead to hypochromic anemia.
- Severe gastrointestinal complaints (gross bleeding and/or ulceration), requiring discontinuation and immediate treatment. Patients receiving high doses and/or long-term treatment should receive gastric protection with high-dosed antacids, ranitidine or omeprazole.
- Frequently, central effects (dizziness, tinnitus, hearing loss, vertigo, centrally mediated vision disturbances, and headaches). The higher the daily dose is, the more likely it is that central nervous system side effects will occur.
- Sweating, seen with high doses, independent from antipyretic action
- Long-term treatment with high doses (arthritis and rheumatic fever): often increased liver enzymes without symptoms, rarely reversible liver damage. The potentially fatal Reye's syndrome may occur, if given to pediatric patients with fever and other signs of infections. The syndrome is due to fatty degeneration of liver cells. Up to 30 percent of those afflicted will eventually die. Prompt hospital treatment may be life-saving. Chronic nephritis with long-term use, usually if used in combination with certain other painkillers. This condition may lead to chronic renal failure.
- Prolonged and more severe bleeding after operations and post-traumatic for up to 10 days after the last aspirin dose. If one wishes to counteract the bleeding tendency, fresh thrombocyte concentrate will usually work.
- Skin reactions, angioedema, and bronchospasm have all been seen infrequently.

Interactions

Aspirin can interact with some other drugs. Some drugs, for example those used for diabetes, are bound by plasma protein in the blood supply and are therefore not free to react with their targets. However, aspirin may displace them from plasma protein, leading to a drug overdose. Aspirin has this same effect on anticoagulants.

Overdose

Aspirin overdose can be acute or chronic. In acute poisoning, a single large dose is taken; in chronic poisoning, supratherapeutic doses are taken over a period of time. Acute overdose has a mortality rate of 2%. Chronic overdose is more commonly lethal with a mortality rate of 25%; chronic overdose may be especially severe in children.[7]

Symptoms

Aspirin overdose has potentially serious consequences, sometimes leading to significant morbidity and mortality. Patients with mild intoxication frequently have nausea and vomiting, abdominal pain, lethargy, tinnitus, and dizziness. More significant symptoms occur in more severe poisonings and include hyperthermia, tachypnea, respiratory alkalosis, metabolic acidosis, hypokalemia, hypoglycemia, hallucinations, confusion, seizure, cerebral edema, and coma. The most common cause of death following an aspirin overdose is cardiopulmonary arrest usually due to pulmonary edema.[8]

Toxicity

The toxic dose of aspirin is generally considered greater than 150 mg per kg of body mass. Moderate toxicity occurs at doses up to 300 mg/kg, severe toxicity occurs between 300 to 500 mg/kg, and a potentially lethal dose is greater than 500 mg/kg.[9] This is the equivalent of many dozens of the common 325 mg tablets, depending on body weight. Please note that children cannot tolerate as much aspirin per unit body weight as adults can, even when aspirin is indicated. Label-directions should be followed carefully.

Treatment

All overdose patients must be taken to a hospital immediately. Contrary to the urban legend, one can die from ingesting a bottle of pills, even if they are subsequently thrown up.

Initial treatment of an acute overdose includes gastric decontamination of the patient. This is achieved by administering activated charcoal which adsorbs the aspirin in the gastrointestinal tract, stomach pumps are no longer routinely used in the treatment of poisonings but are sometimes considered if the patient has ingested a potentially lethal amount up to 1 hour previously.[10] Repeated doses of charcoal have been proposed to be beneficial in aspirin overdose.[11] A study performed found that repeat dose charcoal might not be of significant value.[12] However, most toxicologists will administer additional charcoal if serum salicylate levels are increasing.

Patients are monitored until their peak salicylate blood level has been determined.[13] Blood levels are usually performed 4 hours after ingestion and then every 2 hours after that to determine the maximum level. Maximum levels can be used as a guide to toxic effects expected.[14]

There is no antidote to salicylate poisoning. Frequent blood work is performed to check metabolic, salicylate, and blood sugar levels; arterial blood gas assessments are performed to test for respiratory alkalosis and metabolic acidosis. Patients are monitored and often treated according to their individual symptoms, patients may be given intravenous potassium chloride to counteract hypokalemia, glucose to restore blood sugar levels, benzodiazepines for any seizure activity, fluids for dehydration, and importantly sodium bicarbonate to restore the blood's sensitive pH balance. Sodium bicarbonate also has the effect of increasing the pH of urine, which in turn increases the elimination of salicylate. Additionally, hemodialysis can be implemented to enhance the removal of salicylate from the blood. Hemodialysis is usually used in severely poisoned patients; for example, patients with significantly high salicylate blood levels, significant neurotoxicity (agitation, coma,

convulsions), renal failure, pulmonary edema, or cardiovascular instability are hemodialyzed.[13] Hemodialysis also has the advantage of restoring electrolyte and acid-base abnormalities; hemodialysis is often life-saving in severely ill patients.

If the overdose was intentional, the patient should undergo psychiatric evaluation, as with any suicide attempt.

Epidemiology

In the later part of the 20th century the number of salicylate poisonings has declined mainly due to the popularity of other over-the-counter analgesics such as paracetamol. Fifty-two deaths involving single-ingredient aspirin were reported in the United States in the year 2000.[15]

Research into cancer prevention

The role that aspirin might have in reducing the rates of certain cancers has been the subject of many studies. However, given the side effects of NSAIDs on increased gastrointestinal bleeding and rates of heart disease, there is no current medical recommendation to use these drugs for cancer reduction.

- *Prostate* - While there is some epidemiological information suggesting a correlation between the reduction of prostate cancer and aspirin use, two recent studies (a multicentric case-control study and epidemiological study) were inconclusive.[16][17]
- *Colon* - A 2005 JAMA article states that aspirin may prevent carcinoma of the colon, when taken in at least twice-daily adult (325 mg) doses.[18] It follows an earlier study, also using the Nurses' Health Study (NHS) women, which had similar conclusions but with a smaller testing population.[19] The conclusions of the studies were that both aspirin and other non-aspirin NSAIDs used over a long time (best results seen after at least a decade of regular use) reduce risk of colorectal cancer. The risk was reduced the most at doses higher than 14 325 mg tablets per week (full-strength aspirin twice a day). However, these doses can have a higher incidence of serious gastrointestinal bleeding, and reduced doses (even the low doses recommended for cardiovascular health (81 mg/day)) also seem to have an anti-cancer effect, albeit not as much as the higher doses.
- *Gall Bladder* - There is some evidence that aspirin may increase gall bladder motility and thus be effective in treating gall bladder disease.
- *Pancreatic* - A study in 2004 showed that increases in dose and duration of aspirin may significantly increase the risk of pancreatic cancer in women (only women were in the study); however this did not seem to affect current, regular users.[20]
- *Upper GI Tract* - A study published in 2003 reported that people who had been taking aspirin regularly for 5 or more years seemed to have a two-thirds less risk of mouth, throat and esophageal cancer than non-users.[21] This study

was done on both cancer patients and other people in hospital for various reasons, and was done by comprehensive epidemiological questionnaires of life habits rather than empirical testing.

- *Lung* - A 20-year study published in 2002 showed that in a group of 14,000 women in New York City, regular aspirin use (defined as at least once a week, various doses) reduced their risk of lung cancer, especially small-cell carcinoma. [22] This may be because many lung tumors have high amounts of COX-2 enzymes expressed in them, especially in adenocarcinomas and tumors caused by asbestosis. [23] Aspirin is a known blocker of both COX-1 and COX-2 enzymes, although this study suggests that if the COX-2 link is direct, other COX-2 inhibitors may also play a similar role. Another study in 2002 of both men and women found that risk reduction was more significant in males than females; overall, the effects of smoking were far more influential than aspirin use in determining cancer risks. [24] Of those who smoked, those who smoked the least got the most benefit from aspirin use. Some of the heaviest smokers saw no benefit from aspirin at all.

Diclofenac

Systematic (IUPAC) name

*2-[2-(2,6-dichlorophenyl)
aminophenyl]ethanoic acid*

Identifiers

CAS number 15307-86-5

ATC code M01AB05 M02AA15, S01BC03

PubChem 3033

DrugBank APRD00527

Chemical data

Formula $C_{14}H_{11}NCl_2O_2$

Mol. weight 296.148 g/mol

Pharmacokinetic data

Bioavailability **100%**

Protein binding more than 99%

Metabolism hepatic, no active metabolites exist

Half life 1.2-2 hr (35% of the drug enters enterohepatic recirculation)

Excretion biliary, only 1% in urine

Therapeutic considerations

Pregnancy cat. A(AU) B (1st. and 2nd. trimenon), X (third trimenon)

Legal status POM(UK) Rx-only most preparations/countries. Limited OTC some countries

Routes oral, rectal, im, iv (renal- and gallstones), topical

Diclofenac (marketed as *Voltaren*®, *Voltarol*®, *Diclon*®, *Dicloflex*® *Difen*, *Difene*, *Cataflam*® and *Rhumalgan*®) is a non-steroidal anti-inflammatory drug (NSAID) taken to reduce inflammation and an analgesic reducing pain in conditions such as in arthritis or acute injury. It can also be used to reduce menstrual pain.

In the United Kingdom and the United States it may be supplied as either the sodium or potassium salt, while in some other countries only as the potassium salt. Diclofenac is available as a generic drug in a number of formulations. Over the counter (OTC) use is approved in some countries for minor aches and pains and fever associated with common infections.

Diclofenac is well-tolerated after 30 years experience by the general human population, but may unexpectedly become intolerated in some of the elderly population of long term users.

It has been reported that veterinary diclofenac use in India has caused a crash of the vulture population,[1] with "major ecological consequences" and a sub-cultural Zoroastrian Parsi "sky burial" crisis.[2] Diclofenac causes kidney failure in vultures that eat treated domestic animals.

Mechanism of action

The action of one single dose is much longer (6 to 8 hours) than the very short half-life of the drug indicates. This could partly be due to a particular high concentration achieved in synovial fluids.

The exact mechanism of action is not entirely known, but it is thought that the primary mechanism responsible for its anti-inflammatory/antipyretic/analgesic action is inhibition of prostaglandin synthesis by inhibition of cyclooxygenase (COX).

Inhibition of COX also decreases prostaglandins in the epithelium of the stomach, making it more sensitive to corrosion by gastric acid. This is also the main side effect of diclofenac. Diclofenac has a low to moderate preference to block the COX2-isoenzyme (approximately 10-fold) and is said to have therefore a somewhat lower incidence of gastrointestinal complaints than noted with indomethacin and aspirin.

Diclofenac may also be a unique member of the NSAIDs. There is some evidence that diclofenac inhibits the lipooxygenase pathways, thus reducing formation of the leukotrienes (also pro-inflammatory autacoids). There is also speculation that diclofenac may inhibit phospholipase A***2*** as part of its mechanism of action. These additional actions may explain the high potency of diclofenac - it is the most potent NSAID on a molar basis.

There are marked differences among NSAIDs in their selective inhibition of the two subtypes of cyclo-oxygenase, COX-1 and COX-2. Much pharmaceutical drug design has attempted to focus on selective COX-2 inhibition as a way to minimize the gastrointestinal side effects of non-selective NSAIDs like aspirin. In practice, use of some COX-2 inhibitors has led to massive numbers of patient family lawsuits alleging wrongful death by heart attack, yet other significantly COX-selective NSAIDs like diclofenac have been well-tolerated by most of the population.

Indications

Diclofenac is used for musculoskeletal complaints, especially arthritis (rheumatoid arthritis, osteoarthritis, spondylarthritis, ankylosing spondylitis), gout attacks, and pain management in case of kidney stones and gallstones. An additional indication is the treatment of acute migraines. Diclofenac is used commonly to treat mild to moderate post-operative or post-traumatic pain, particular when inflammation is also present, and is effective against menstrual pain.

As long-term use of diclofenac and similar NSAIDs predisposes for peptic ulcer, many patients at risk for this complication are prescribed a combination (Arthrotec®) of

diclofenac and misoprostol, a synthetic prostaglandin analogue, to protect the gastric mucosa.

An external, gel-based form of diclofenac (Solareze®) is available for the treatment of facial actinic keratosis which is caused by over-exposure to sunlight. Some countries have also approved the external use of diclofenac gel to treat muskoskeletal conditions.

Over-the-counter use against minor aches and pains and fever associated with common infections is also licensed in some countries.

In many countries eye-drops are sold to treat acute and chronic non-bacterial inflammations of the anterior part of the eyes (e.g. postoperative states). A common brand name is Voltaren-ophta®.

Off label/investigational uses

Diclofenac is often used to treat chronic pain associated with cancer, particular if inflammation is also present (Step I of the World Health Organisation (WHO) Scheme for treatment of chronic pain). Good results (sometimes better than those with opioids) have been seen in female breast cancer and in the pain associated with bony metastases. Diclofenac can be combined with opioids if needed. In Europe Combaren® exists, a fixed combination of diclofenac and codeine (50 mg each) for cancer treatment. Combinations with psychoactive drugs such as chlorprothixene and/or amitriptyline have also been investigated and found useful in a number of cancer patients.

Fever due to malignant lymphogranulomatosis (Hodgkin's lymphoma) often responds to diclofenac. Treatment can be terminated as soon as the usual treatment with radiation and/or chemotherapy causes remission of fever.

Diclofenac may prevent the development of Alzheimer's disease if given daily in small doses during many years. All investigations were stopped after it was found that some of the other investigated NSAIDs (naproxen, rofecoxib) caused a higher incidence of death cases due to cardiovascular events and stroke compared to placebo.

Diclofenac has been found to increase the blood pressure in patients with Shy-Drager syndrome (autonomous hypotension) often seen in diabetic patients. Currently, this use is highly investigational and cannot be recommended as routine treatment.

Contraindications

- Hypersensitivity against diclofenac
- History of allergic reactions (bronchospasm, shock, rhinitis, urticaria) following the use of Aspirin or another NSAID
- Third-trimester pregnancy
- Active stomach and/or duodenal ulceration or gastrointestinal bleeding
- Inflammative intestinal disorders such as Crohn's disease or ulcerative colitis
- Severe insufficiency of the heart (NYHA III/IV)

- Recently, a warning has been issued by FDA not to treat patients recovering from heart surgery
- Severe liver insufficiency (Child-Pugh Class C)
- Severe renal insufficiency (creatinine clearance <30 ml/min)
- Caution in patients with preexisting hepatic porphyria, as diclofenac may trigger attacks
- Caution in patients with severe, active bleeding such as cerebral hemorrhage

Side effects

- Diclofenac is among the better tolerated NSAIDs. Though 20% of patients on long-term treatment experience side effects, only 2% have to discontinue the drug, mostly due to gastrointestinal complaints.
- Gastrointestinal complaints are most often noted (see above). The development of ulceration and/or bleeding requires immediate termination of treatment with diclofenac. Most patients receive an ulcer-protective drug as prophylaxis during long-term treatment (misoprostol, ranitidine 150mg at bedtime or omeprazole 20 mg at bedtime).
- Bone marrow depression is noted infrequently (leukopenia, agranulocytosis, thrombopenia with/without purpura, aplastic anemia). These conditions may be life-threatening and/or irreversible, if detected too late. All patients should be monitored closely. Diclofenac is a weak and reversible inhibitor of thrombocytic aggregation needed for normal coagulation.
- Liver and renal damage occur infrequently, but are usually reversible. Hepatitis may occur rarely without any warning symptoms and may be fatal. Patients with osteoarthritis develop more often symptomatic liver disease than patients with rheumatoid arthritis. Liver and kidney function should be monitored regularly during long-term treatment. If used for the shortterm treatment of pain or fever, diclofenac has not been found to be more hepatotoxic than other NSAIDs.
- Diclofenac is specifically known to cause kidney failure in Asian vultures. Species and individual humans that are drug sensitive are initially assumed to lack genes expressing specific drug detoxification enzymes. Because elderly humans have reduced expression levels of all enzymes, elderly human metabolisms may gradually approach those of vultures, thus unexpectedly becoming more diclofenac intolerant.
- NSAIDs "are associated with adverse renal [kidney] effects caused by the reduction in synthesis of renal prostaglandins"[3] in sensitive persons or animal species, and potentially during long term use in non-sensitive persons if resistance to side effects decreases with age. Unfortunately this side effect can't be avoided merely by using a COX-2 selective inhibitor because, "Both isoforms of COX, COX-1 and COX-2, are expressed in the kidney... Consequently, the same precautions regarding renal risk that are followed for nonselective NSAIDs should be used when selective COX-2 inhibitors are administered."[3]
- Following the identification of increased risks of heart attacks with the selective COX-2 inhibitor rofecoxib in 2004, attention has focused on all the other members of the NSAIDs group, including Diclofenac. Research results are mixed with a meta-analysis of papers and reports upto April 2006 suggesting a relative increased rate of heart disease of 1.63 compared to non users.[4] Professor Peter Weissberg, Medical Director of the British Heart Foundation said, "However, the increased risk is small and many patients with chronic debilitating pain may well feel that this small risk is worth taking to relieve their symptoms". Only naproxen

was found not to increase the risk of heart disease, however this is known to have a higher rate of gastric ulceration than Diclofenac. A subsequent large study of 74,838 users of NSAIDs or coxibs, published in May 2006 found no additional cardiovascular risk from Diclofenac use.[5]

Formulations

Voltaren and Voltarol contain the sodium salt of diclofenac. In the United Kingdom Voltarol can be supplied with either the sodium salt or potassium salt, while Cataflam in some other countries is the potassium salt only.

Diclofenac is available in stomach acid resistant formulations (25 and 50 mg), fast disintegrating oral formulations (50 mg), slow- and controlled-release forms (75, 100 or 150 mg), suppositories (50 and 100 mg), and injectable forms (50 and 75 mg).

Diclofenac is also available over the counter (OTC) in some countries: Voltaren® dolo (12.5 mg diclofenac as potassium salt) in Switzerland and Germany, and preparations with 25 mg diclofenac are OTC in New Zealand.

Ecological problems

Use of diclofenac in animals has been reported to have led to a sharp decline in the vulture population in the Indian subcontinent, up to 95% in some areas.[6] The mechanism is probably renal failure, a known side-effect of diclofenac. Vultures eat the carcasses of domesticated animals that have been administered veterinary diclofenac, and are poisoned by the accumulated chemical. At a meeting of the National Wildlife Board in March 2005, the Government of India announced that it intended to phase out the veterinary use of diclofenac.[7]Meloxicam is a safer (though more expensive) candidate to replace use of diclofenac.[2]

"The loss of tens of millions of vultures over the last decade has had major ecological consequences across the Indian subcontinent that pose a potential threat to human health. In many places, populations of feral dogs (Canis familiaris) have benefited from the disappearance of Gyps vultures as the main scavenger of wild and domestic ungulate carcasses. Associated with the rise in dog numbers is an increased risk of human cases of rabies."[2]

The Government of India cites one of those major consequences as a vulture species extinction.[7] Westerners may not initially appreciate how a major shift in transfer of corpse pathogens from vultures to feral dogs and rats can lead to a disease pandemic causing millions of deaths in a crowded country like India.

The loss of vultures has had a social impact on the Indian Zoroastrian Parsi community, who traditionally use vultures to dispose of human corpses in "sky burials", and are now having to seek alternative disposal methods.[2]

Pregnancy cat. $C_{(AU)}$ $D_{(US)}$

Legal status $S2_{(AU)}$ $GSL_{(UK)}$ $OTC_{(US)}$

Routes Oral, rectal and topical

Ibuprofen (INN) (IPA: [Èajbjuprof[n]) is a non-steroidal anti-inflammatory drug (NSAID) widely marketed under various trademarks including *Herron Blue*, *Act-3*, *Advil*, *Brufen*, *Motrin*, *Nuprin*, *Dorival* and *Nurofen*. It is used for relief of symptoms of arthritis, primary dysmenorrhoea, fever, and as an analgesic, especially where there is an inflammatory component. Ibuprofen was developed by the research arm of Boots Group.

Clinical use

Low doses of ibuprofen (200 mg, and sometimes 400 mg) are available over the counter (OTC) in most countries. Ibuprofen has a dose-dependent duration of action of approximately 4–8 hours, which is longer than suggested by its short half-life. The recommended dose varies with body mass and indication. Generally, the oral dose is 200–400 mg (5–10 mg/kg in children) every 4–6 hours, up to a usual maximum daily dose of 800–1200 mg. Under medical direction, a maximum daily dose of 3200 mg may sometimes be used.

Off-Label and investigational use

- As with other NSAIDs, ibuprofen may be useful in the treatment of severe orthostatic hypotension.[1]

- In some studies, ibuprofen showed superior results compared to placebo in the prophylaxis of Alzheimer's disease, when given in low doses over a long time.[2] Further studies are needed to confirm the results before ibuprofen can be recommended for this indication.
- Ibuprofen has been associated with a lower risk of Parkinson's disease, and may delay or prevent Parkinson's disease. Aspirin, other NSAIDs, and paracetamol had no effect on the risk for Parkinson's.[3] Further research is warranted before recommending ibuprofen for this use.

Ibuprofen lysine

In Europe, Australia, and New Zealand, *ibuprofen lysine* (ibuprofenlysinat, the lysine salt of ibuprofen) is licensed for treatment of the same conditions as ibuprofen. Ibuprofen lysine has been shown to have a more rapid onset of action compared to base ibuprofen.[4]

Mechanism of action

Ibuprofen is an NSAID which is believed to work through inhibition of cyclooxygenase (COX), thus inhibiting prostaglandin synthesis. There are at least 2 variations of cyclooxygenase (COX-1 and COX-2), ibuprofen inhibits both COX-1 and COX-2. It appears that its analgesic, antipyretic, and anti-inflammatory activity are achieved principally through COX-2 inhibition; whereas COX-1 inhibition is responsible for its unwanted effects on platelet aggregation and the GI mucosa.

Main article: Non-steroidal anti-inflammatory drug

Adverse effects

Ibuprofen appears to have the lowest incidence of gastrointestinal adverse drug reactions (ADRs) of all the non-selective NSAIDs. However, this only holds true at lower doses of ibuprofen, so over-the-counter preparations of ibuprofen are generally labelled to advise a maximum daily dose of 1,200 mg.

Main article: Non-steroidal anti-inflammatory drug

Reported adverse drug reactions

In low single doses (200 to 400 mg) and daily doses of up to 1,200 mg the incidence of side effects is low. However, in patients treated on a long-term basis with more than 1,200 mg daily discontinuation rates are as high as 10 to 15%.

Common adverse effects include: nausea, dyspepsia, gastrointestinal ulceration/bleeding, raised liver enzymes, diarrhea, headache, dizziness, salt and fluid retention, hypertension.[5]

Infrequent adverse effects include: oesophageal ulceration, heart failure, hyperkalaemia, renal impairment, confusion, bronchospasm, rash.[5]

Photosensitivity

As with other NSAIDs, ibuprofen has been reported to be a photosensitising agent.[6][7] However, this only rarely occurs with ibuprofen and it is considered to be a very weak photosensitising agent when compared with other members of the 2-arylpropionic acids. This is because the ibuprofen molecule contains only a single phenyl moiety and no bond conjugation, resulting in a very weak chromophore system and a very weak absorption spectrum which does not reach into the solar spectrum.

Cardiovascular risk

Along with several other NSAIDs, ibuprofen has been implicated in elevating the risk of myocardial infarction, particularly among those chronically using high doses.[8]

Stereochemistry

Ibuprofen, like other 2-arylpropionate derivatives (including ketoprofen, flurbiprofen, naproxen, etc) contains a chiral carbon in the ±-position of the propionate moiety. As such there are two possible enantiomers of ibuprofen with the potential for different biological effects and metabolism for each enantiomer.

Indeed it was found that (S)-(+)-ibuprofen (dexibuprofen) was the active form both in vitro and in vivo.

It was logical, then, that there was the potential for improving the selectivity and potency of ibuprofen formulations by marketing ibuprofen as a single-enantiomer product (as occurs with naproxen, another NSAID.).

Further in vivo testing, however, revealed the existence of an isomerase which converted (R)-ibuprofen to the active (S)-enantiomer. Thus, due to the expense and futility that might be involved in marketing the single-enantiomer, most ibuprofen formulations currently marketed are racemic mixtures. A notable exception to this is *Seractiv* (Nordic Drugs).

Human toxicology

Ibuprofen overdose has become common since it was licensed for over-the-counter use. There are many overdose experiences reported in the medical literature.[9] Human response in cases of overdose ranges from absence of symptoms to fatal outcome in spite of intensive care treatment. Most symptoms are an excess of the pharmacological action of ibuprofen and include abdominal pain, nausea, vomiting, drowsiness, dizziness, headache, tinnitus, and nystagmus. Rarely more severe symptoms such as gastrointestinal bleeding, seizures, metabolic acidosis, hyperkalaemia, hypotension, bradycardia, tachycardia, atrial fibrillation, coma, hepatic dysfunction, acute renal failure, cyanosis, respiratory depression, and cardiac arrest have been reported.[10]. The severity of symptoms varies with the ingested dose and the time elapsed, however, individual sensitivity also plays an important role. Generally, the symptoms observed with an overdose of ibuprofen are similar to the symptoms caused by overdoses of other NSAIDs.

There is little correlation between severity of symptoms and measured ibuprofen plasma levels. Toxic effects are unlikely at doses below 100 mg/kg but can be severe above 400 mg/kg;[11] however, large doses do not indicate that the clinical course is likely to be lethal.[12] It is not possible to determine a precise lethal dose, as this may vary with age, weight, and concomitant diseases of the individual patient.

Therapy is largely symptomatic. In cases presenting early, gastric decontamination is recommended. This is achieved using activated charcoal; charcoal absorbs the drug before it can enter the systemic circulation. Gastric lavage is now rarely used, but can be considered if the amount ingested is potentially life threatening and it can be performed within 60 minutes of ingestion. Emesis is not recommended.[13] The majority of ibuprofen ingestions produce only mild effects and the management of overdose is straightforward. Standard measures to maintain normal urine output should be instituted and renal function monitored.[11] Since ibuprofen has acidic properties and is also excreted in the urine, forced alkaline diuresis is theoretically beneficial. However, due to the fact ibuprofen is highly protein bound in the blood, there is minimal renal excretion of unchanged drug. Forced alkaline diuresis is therefore of limited benefit.[14] Symptomatic therapy for hypotension, GI bleeding, acidosis, and renal toxicity may be indicated. Occasionally, close monitoring in an intensive care unit for several days is necessary. If a patient survives the acute intoxication, he/she will usually experience no late sequelae.

Availability

Ibuprofen was made available under prescription in the United Kingdom in 1969. In the years since, the good tolerability profile along with extensive experience in the community (otherwise known as Phase IV trials), has resulted in the rescheduling of small packs of ibuprofen to allow availability over-the-counter in pharmacies worldwide. Indeed there has been an increasing trend towards descheduling ibuprofen such that it is now available in supermarkets and other general retailers. The wider availability has meant that ibuprofen is now almost as commonly used as aspirin and paracetamol.

***Legal status P**rescription only*

Routes Oral, rectal, IV, topical

Indometacin (INN) or *Indomethacin* (USAN and former BAN) is a non-steroidal anti-inflammatory drug commonly used to reduce fever, pain, stiffness, and swelling. It works by inhibiting the production of prostaglandins, molecules known to cause these symptoms. It is marketed under many trade names, including *Indocin*, *Indocid*, *Indochron E-R*, and *Indocin-SR*.

Chemical properties

Indometacin is a methylated indole derivative and a member of the arylalkanoic acid class of NSAIDs, which includes diclofenac.

Indications

Clinical indications for indometacin include:

- ankylosing spondylitis
- rheumatoid arthritis
- arthritic gout
- osteoarthritis
- juvenile arthritis
- psoriatic arthritis
- Reiter's syndrome
- Paget's disease of bone
- Bartter syndrome
- pseudogout
- dysmenorrhea (menstrual cramps)
- pericarditis
- bursitis
- tendinitis
- nephrogenic diabetes insipidus (prostaglandin inhibits vasopressin's action in the kidney)
- fever and pain associated with malignant diseases (tumors, bony metastases, lymphogranulomatosis)
- Paroxysmal hemicrania, hemicrania continua and migraine

Indometacin has also been used clinically to delay premature labor, reduce amniotic fluid in polyhydramnios, and to treat patent ductus arteriosus.

Indometacin is a potent drug with many serious side effects and should not be considered an analgesic for minor aches and pains or fever. The drug is more potent than aspirin, but is not a better analgesic. In mild to moderate pain a standard oral dose of indometacin proved as effective as 600mg aspirin.

Contraindications

- concurrent peptic ulcer, or history of ulcer disease
- allergy to indometacin, aspirin, or other NSAIDs
- patients with nasal polyps reacting with an angioedema to other NSAIDs
- children under 2 years of age (with the exception of neonates with patent ductus arteriosus)
- severe preexisting renal and liver damage
- caution : preexisting bone marrow damage (frequent blood cell counts are indicated)

caution : bleeding tendencies of unknown origin (indometacin inhibits platelet aggregation)
caution : Parkinson's disease, epilepsy, psychotic disorders (indometacin may worsen these conditions)

Mechanism of action

Main article: Non-steroidal anti-inflammatory drug

Indometacin is a nonselective inhibitor of cyclooxygenase (COX) 1 and 2, enzymes that participate in prostaglandin synthesis from arachidonic acid. Prostaglandins are hormone-like molecules normally found in the body, where they have a wide variety of effects, some of which lead to pain, fever, and inflammation.

Prostaglandins also cause uterine contractions in pregnant women. Indometacin is an effective tocolytic agent, able to delay premature labor by reducing uterine contractions through inhibition of PG synthesis in the uterus and possibly through calcium channel blockade.

Indometacin has two additional modes of actions with clinical importance:

- It inhibits motility of polymorphonuclear leucocytes, similar to colchicine.
- It uncouples oxidative phosphorylation in cartilaginous (and hepatic) mitochondria, like salicylates.

These additional effects account as well for the analgesic and the anti-inflammatory properties.

Indometacin readily crosses the placenta, and can reduce fetal urine production to treat polyhydramnios. It does so by reducing renal blood flow and increasing renal vascular resistance, possibly by enhancing the effects of vasopressin on the fetal kidneys.

Adverse effects

Since indometacin inhibits both COX-1 and COX-2, it inhibits the production of prostaglandins in the stomach and intestines which maintain the mucous lining of the gastrointestinal tract. Indometacin, therefore, like other nonselective COX inhibitors, can cause peptic ulcers. The ulcers can result in serious bleeding and/or perforation requiring hospitalization of the patient. Some even die from these complications. To reduce the possibility of peptic ulcers, indometacin should be prescribed at the lowest dosage needed to achieve a therapeutic effect, usually between 50–200 mg/day. It should always be taken with food. Nearly all patients benefit from an ulcer protective drug (e.g. highly dosed antacids, ranitidine 150mg at bedtime, or omeprazole 20mg at bedtime). Other common gastrointestinal complaints, including dyspepsia, heartburn and mild diarrhea are less serious and rarely require discontinuation of indometacin.

Many NSAIDs, but particularly indometacin, cause lithium retention by reducing its excretion by the kidneys. Thus indometacin users have an elevated risk of lithium toxicity. For patients taking lithium supplements (e.g. for treatment of depression or bipolar disorder), less toxic NSAIDs such as sulindac or aspirin, are preferred.

Indometacin also reduces plasma renin activity and aldosterone levels, and increases sodium and potassium retention. It also enhances the effects of vasopressin. Together these may lead to:

- edema (swelling due to fluid retention)
hyperkalemia (high potassium levels)
hypernatremia (high sodium levels)
hypertension (high blood pressure)

The drug may also cause elevations of serum creatinine and more serious renal damage such as acute renal failure, chronic nephritis and nephrotic syndrome. These conditions also often begin with edema and hyperkalema.

Additionally, indometacin quite often causes headache (10 to 20%), sometimes with vertigo and dizziness, hearing loss, tinnitus, blurred vision (with or without retinal damage) and worsens Parkinson's disease, epilepsy, and psychiatric disorders. Cases of life-threatening shock (including angioedema, sweating, severe hypotension and tachycardia as well as acute bronchospasm), severe or lethal hepatitis and severe bone marrow damage have all been reported. Skin reactions and photosensitivity are also possible side effects.

Due to its strong antipyretic activity indometacin may obscure the clinical course of serious infections.

The frequency and severity of side effects and the availability of better tolerated alternatives make indometacin today a drug of second choice. Its use in acute gout attacks and in dysmenorrhea is well-established because in these indications the duration of treatment is limited to a few days only, therefore serious side effects are not likely to occur.

Necessary Examinations during Longterm Treatment

Patients should undergo regular physical examination to detect edema and signs of central nervous side effects. Blood presssure checks will reveal development of hypertension. Periodic serum electrolyte (sodium, potassium, chloride) measurements, complete blood cell counts and assessment of liver enzymes as well as of creatinine (renal function) should be performed. This is particularly important if indometacin is given together with an ACE inhibitor or with potassium-sparing diuretics, because these combinations can lead to hyperkalemia and/or serious kidney failure. No examinations are necessary if only the topical preparations (spray or gel) are applied.

Animal Toxicity and Human Overdose

Indomethacin has a high acute toxicity both for animals (12 mg/kg in rats and 50 mg/kg in mice) and for humans. Exact human data does not exist, but some fatal human cases, particularly in children and adolescents, have been seen.

Generally, overdose in humans causes drowsiness, dizziness, severe headache, mental confusion, paraesthesia, numbness of limbs, nausea and vomiting. Severe gastrointestinal bleeding is also possible. Cerebral edema, and cardiac arrest with fatal outcome have been seen in children.

The treatment is symptomatic and largely the same as with diclofenac. However, the possibility of severe GI tract symptoms should be particularly noted.

The risk of overdose after exaggerated local treatment with gel or spray is very limited.

Usual Dosage Forms

- Tablets or Capsules 25 and 50mg
- Suppositories 50 and 100mg
- Modified-release Capsules 75mg
- Syrup (25mg/5ml)
- Injectable concentrate 50mg for i.m. injection
- Spray or Gel
- Patches containing 0.5% by weight
- 1% topical liquid

History

Indometacin was discovered in 1963 and it was first approved for use in the U.S. by the Food and Drug Administration in 1965. Its mechanism of action, along with several other NSAIDs that inhibit COX, was described in 1971.

Half life 2-2.5 hours

Ketoprofen, *(RS)2-(3-benzoylphenyl)-propionic acid* (chemical formula C***16***H***14***O***3***) is one of the propionic acid class of non-steroidal anti-inflammatory drug (NSAID) with analgesic and antipyretic effects. It acts by inhibiting the body's production of prostaglandin.

Ketoprofen was available over-the-counter in the United States in the form of 12.5mg coated tablets (Orudis KT®), but the product has been discontinued. It is available by prescription as 25, 50, 75, 100, 150, and 200mg capsules.

Ketoprofen also comes in a 2,5% gel for topical application.

Brand names in the US are *Orudis* and *Oruvail*.

Naproxen (INN) (IPA: [nYÈprRksYn]) is a non-steroidal anti-inflammatory drug (NSAID) commonly used for the reduction of mild to moderate pain, fever, inflammation and stiffness caused by conditions such as osteoarthritis, rheumatoid arthritis, psoriatic arthritis, gout, ankylosing spondylitis, injury (like fractures), menstrual cramps, tendonitis, bursitis, and the treatment of primary dysmenorrhea. Naproxen and *naproxen sodium* are marketed under various trade names including: *Aleve*, *Anaprox*, *Naprogesic*, *Naprosyn*, *Naprelan*.

Naproxen was first marketed as the prescription drug Naprosyn in 1976 and naproxen sodium was first marketed under the trade name Anaprox in 1980. It remains a prescription-only drug in much of the world. The U.S. Food and Drug Administration (FDA) approved the use of naproxen sodium as an over-the-counter (OTC) drug in 1991, where OTC preparations are sold under the trade name Aleve. In Australia, small packets of lower-strength preparations of naproxen sodium are Schedule 2 Pharmacy Medicines.

Structure and details

Naproxen is a member of the 2-arylpropionic acid (profen) family of NSAIDs. It is an odorless, white to off-white crystalline substance. It is lipid-soluble, practically insoluble in water with a low pH (below pH 4), while freely soluble in water at 6 pH and above. Naproxen has a melting point of 153 °C.

Adverse effects and warnings

Like other NSAIDs, naproxen is capable of producing disturbances in the gastrointestinal tract. Taking the medication with food may help to alleviate this most commonly reported adverse effect.

Also like other NSAIDs, naproxen can inhibit the excretion of sodium and lithium. Extreme care must be taken by those who use this drug along with lithium supplements.

Naproxen is also not recommended for use with NSAIDs of the salicylate family (drugs may reduce each other's effects), nor with anticoagulants (may increase risk of bleeding).

Certain preparations of Naproxen are not recommended for use in patients with hypertension, as they contain sodium, worsening the effects of hypertension.

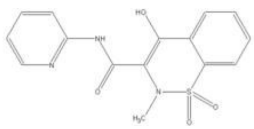
In August 2006, the journal Birth Defects Research Part B published results in the September issue indicating that pregnant women who take NSAIDs including Naproxen in the first trimester run an increased risk of having a child with congenital birth defects, particularly heart anomalies.

In December 2004, the FDA issued a press release following the decision by the National Institutes of Health to halt a five-year study, called the Alzheimer's Disease Anti-Inflammatory Prevention Trial. That study aimed to test both Aleve and Celebrex as preventives for Alzheimer's disease. Preliminary information from the study showed naproxen elevated the risk of heart attack and stroke by 50%. The FDA advised patients taking over-the-counter naproxen products to:

- carefully follow the instructions on the label,
- avoid exceeding the recommended doses for naproxen (220 milligrams twice daily), and

- take naproxen for no longer than ten days unless a physician directs otherwise.

Piroxicam



Systematic (IUPAC) name

9-(hydroxy-pyridin-2-ylamino-methylidene)- 8-methyl-7,7-dioxo-7$l^{6}-thia-8-azabicyclo[4.4.0] deca-1,3,5-trien-10-one

Identifiers

Formula $C_{15}H_{13}N_{3}O_{4}S$

Mol. weight 331.348 g/mol

Pharmacokinetic data

Metabolism 4-10% renal

Half life 30 to 86 hours

Excretion 4-10% renal

Therapeutic considerations

Pregnancy cat. C, D if used in the third trimester or near delivery

Piroxicam (US trade name *Feldene*) is a nonsteroidal anti-inflammatory drug used to relieve the symptoms of arthritis, primary dysmenorrhoea, pyrexia; and as an analgesic, especially where there is an inflammatory component. It is also used in veterinary medicine

to treat certain neoplasias expressing cyclooxygenase (COX) receptors, such as bladder, colon, and prostate cancers.

Mechanism of action

Main article: Non-steroidal anti-inflammatory drug

Piroxicam is an NSAID and, as such, is a non-selective COX inhibitor possessing both analgesic and antipyretic properties.

Adverse effects

Main article: Non-steroidal anti-inflammatory drug

Piroxicam use can result in gastrointestinal toxicity, tinnitus, dizziness, headache, rash, and pruritus. The most severe adverse reactions are peptic ulceration and gastrointestinal bleeding. Approximately 30% of all patients receiving daily doses of 20 mg of piroxicam experience side effects.[1]

Rofecoxib (IPA: [rofYÈkRksjb]) is a nonsteroidal anti-inflammatory drug (NSAID) developed by Merck & Co. to treat osteoarthritis, acute pain conditions, and dysmenorrhoea. Rofecoxib was approved safe and effective by the Food and Drug Administration (FDA) on May 20, 1999 and was subsequently marketed under the brand name *Vioxx*, *Ceoxx* and *Ceeoxx*.

Rofecoxib gained widespread acceptance among physicians treating patients with arthritis and other conditions causing chronic or acute pain. Worldwide, over 80 million people were prescribed rofecoxib at some time.

On September 30, 2004, Merck voluntarily withdrew rofecoxib from the market because of concerns about increased risk of heart attack and stroke. Rofecoxib was one of the most widely used drugs ever to be withdrawn from the market. In the year before withdrawal, Merck had sales revenue of US$2.5 billion from Vioxx.(need source)

Rofecoxib was available on prescription as tablets and as an oral suspension.

Non-Steroidal Anti-Inflammatory Drugs

Rofecoxib belongs to a class of pain relievers called non-steroidal anti-inflammatory drugs or NSAIDS. This class includes many medications sold either over the counter – such as ibuprofen (Advil) and naproxen (Aleve) or by prescription – such as oxaprozin (Daypro) and diclofenac (Voltaren). Like aspirin, which is sometimes classified as an NSAID, traditional NSAIDS work by inhibiting cyclooxygenase (COX), an enzyme that stimulates the synthesis of prostaglandins, chemicals in the body that promote inflammation and pain.

While traditional NSAIDS have long been a mainstay of treatment for patients needing pain relief, this relief does not come without significant adverse side effects—namely a great increase in the risk of gastrointestinal perforations, ulcers, and bleeds or PUBs. Scientists have estimated that NSAID-induced PUBs have caused more than 16,500 deaths and 100,000 hospitalizations annually in the United States. (Wolfe, MM et al, 1999)

The COX Enzyme

In the early 1990s, scientists discovered that the COX enzyme had two forms, now called COX-1 and COX-2. COX-1 mediated the synthesis of prostaglandins responsible for protection of the stomach lining, while COX-2 mediated the synthesis of prostaglandins responsible for pain and inflammation. By creating "selective" NSAIDS that inhibit COX-2, but not COX-1, scientists hypothesized they could offer the same pain relief as traditional NSAIDS, but with greatly reduced risk of fatal or debilitating PUBs.

Rofecoxib is a selective COX-2 inhibitor or coxib (CycloOXygenase-2 InhiBitors). Others include Pfizer's celecoxib (Celebrex) and valdecoxib (Bextra). Interestingly, at the time of its withdrawal, rofecoxib was the only coxib with clinical evidence of its superior gastrointestinal adverse effect profile over conventional NSAIDs. This was largely based on the VIGOR (Vioxx GI Outcomes Research) study, which compared the efficacy and adverse effect profiles of rofecoxib and naproxen. (Bombardier et al., 2000).

Adverse drug reactions

Main article: Non-steroidal anti-inflammatory drug

Aside from the reduced incidence of gastric ulceration, rofecoxib exhibits a similar adverse effect profile to other NSAIDs. Rofecoxib, however, does appear to increase the risk of adverse cardiovascular events (see below).

The chief mechanism proposed to explain rofecoxib's cardiotoxicity is the suppression of prostaglandin, an anti-clotting agent in the blood (Fitzgerald, 2004). COX-2 plays a role in the production of prostaglandin. Because Vioxx inhibits the COX-2 enzyme, prostaglandin production can decrease in endothelial cells and lead to an inefficiency in declumping and vasorelaxtion. Merck, however, argues that there was no effect on prostaglandin production in blood vessels in animal testing] Other researchers have speculated that the cardiotoxicity may be associated with maleic anhydride metabolites formed when rofecoxib becomes ionised under physiological conditions. (Reddy & Corey, 2005)

Vioxx has also been associated with cardiovascular disease, renal (kidney) disease, and heart arrhythmia.

Withdrawal from the market

VIGOR study

The VIGOR (Vioxx GI Outcomes Research) study, which compared the efficacy and adverse effect profiles of rofecoxib and naproxen. (Bombardier et al., 2000), had indicated a

significant 4-fold increased risk of acute myocardial infarction (heart attack) in rofecoxib patients when compared with naproxen patients (0.4% vs 0.1%, RR 0.25) over the 12 month span of the study. The elevated risk began during the second month on rofecoxib. There was no significant difference in the mortality from cardiovascular events between the two groups. Nor was there any significant difference in the rate of myocardial infarction between the rofecoxib and naproxen treatment groups in patients without high cardiovascular risk. The difference in overall risk was accounted for by the patients at higher risk of heart attack: those meeting the criteria for low-dose aspirin prophylaxis of secondary cardiovascular events (previous myocardial infarction, angina, cerebrovascular accident, transient ischemic attack, or coronary artery bypass). (Bombardier et al., 2000)

Merck's scientists interpreted the finding as a protective effect of naproxen, telling the FDA that the difference in heart attacks "is primarily due to" this protective effect (Targum, 2001). Some commentators have noted that naproxen would have to be three times as effective as aspirin to account for all of the difference (Michaels 2005), and some outside scientists warned Merck that this claim was implausible before VIGOR was published. No evidence has since emerged for such a large cardioprotective effect of naproxen, although a number of studies have found protective effects similar in size to those of aspirin (Karha and Topol, 2004; Solomon et al., 2002). Though Dr. Topol's 2004 paper criticized Merck's naproxen hypothesis, he himself co-authored a 2001 JAMA article stating "because of the evidence for an antiplatelet effect of naproxen, it is difficult to assess whether the difference in cardiovascular event rates in VIGOR was due to a benefit from naproxen or to a prothrombotic effect from rofecoxib." (Mukherjee, Nissen and Topol, 2001.)

The results of the VIGOR study were submitted to the United States Food and Drug Administration (FDA) in February 2001, which led to the introduction, in April 2002, of warnings on Vioxx labelling concerning the increased risk of cardiovascular events (heart attack and stroke).

NEJM controversy

Months after the preliminary version of VIGOR was published in the New England Journal of Medicine, the journal editors learned that certain data reported to the FDA was not included in the NEJM article. Several years later, when they were shown a Merck memo during the depositions for the first federal Vioxx trial, they realized that this data had been available to the authors months before publication. The editors wrote an editorial accusing the authors of deliberately withholding the data (Curfman et al, 2006a). They released the editorial to the media on December 8, 2005, before giving the authors a chance to respond. NEJM editor Gregory Curfman explained that the quick release was due to the imminent presentation of his deposition testimony, which he feared would be misinterpreted in the media. He had earlier denied any relationship between the timing of the editorial and the trial. Although his testimony was not actually used in the December trial, Curfman had testified well before the publication of the editorial.

The editors charged that "more than four months before the article was published, at least two of its authors were aware of critical data on an array of adverse cardiovascular events that were not included in the VIGOR article." This additional data included three

additional heart attacks, and raised the relative risk of Vioxx from 4.25-fold to 5-fold. All the additional heart attacks occurred in the group at low risk of heart attack (the "aspirin not indicated" group) and the editors noted that the omission "resulted in the misleading conclusion that there was a difference in the risk of myocardial infarction between the aspirin indicated and aspirin not indicated groups." The relative risk for myocardial infarctions among the aspirin not indicated patients increased from 2.25 to 3 (although it remained statitistically insignificant). The editors also noted a statistically significant (2-fold) increase in risk for serious thromboembolic events for this group, an outcome that Merck had not reported in the NEJM, though it had disclosed that information publicly in March 2000, eight months before publication. (Curfman et al., 2006b, Supplementary Material).

The authors of the study, including the non-Merck authors, responded by claiming that the three additional heart attacks had occurred after the prespecified cutoff date for data collection and thus were appropriately not included. (Utilizing the prespecified cutoff date also meant that an additional stroke in the naproxen population was not reported.) Furthermore, they said that the additional data did not qualitatively change any of the conclusions of the study, and the results of the full analyses were disclosed to the FDA and reflected on the Vioxx warning label. They further noted that all of the data in the "omitted" table was printed in the text of the article. The authors stood by the original article. (Bombardier et al., 2006).

NEJM stood by its editorial, noting that the cutoff date was never mentioned in the article, nor did the authors report that the cutoff for cardiovascular adverse events was before that for gastrointestinal adverse events. The different cutoffs increased the reported benefits of Vioxx (reduced stomach problems) relative to the risks (increased heart attacks). (Curfman et al., 2006b).

Some scientists have accused the NEJM editorial board of making unfounded accusations. Others have applauded the editorial. Renowned research cardiologist Eric Topol, a prominent Merck critic, accused Merck of "manipulation of data" and said "I think now the scientific misconduct trail is really fully backed up". Phil Fontanarosa, executive editor of the prestigious Journal of the American Medical Association, welcomed the editorial, saying "this is another in the long list of recent examples that have generated real concerns about trust and confidence in industry-sponsored studies"

Alzheimer's studies

In 2000 and 2001, Merck conducted several studies of rofecoxib aimed at determining if the drug slowed the onset of Alzheimer's disease. Merck has placed great emphasis on these studies on the grounds that they are relatively large (almost 3000 patients) and compared rofecoxib to a placebo rather than to another pain reliever. These studies found an elevated death rate among rofecoxib patients, although the deaths were not generally heart-related. However, they did not find any elevated cardiovascular risk due to rofecoxib (Konstam et al., 2001). Before 2004, Merck cited these studies as providing evidence, contrary to VIGOR, of rofecoxib's safety.

APPROVe study

In 2001, Merck commenced the APPROVe (Adenomatous Polyp PRevention On Vioxx) study, a three year trial with the primary aim of evaluating the efficacy of rofecoxib for the prophylaxis of colorectal polyps. Celecoxib had already been approved for this indication, and it was hoped to add this to the indications for rofecoxib as well. An additional aim of the study was to further evaluate the cardiovascular safety of rofecoxib.

The APPROVe study was terminated early when the preliminary data from the study showed an increased relative risk of adverse thrombotic cardiovascular events (including heart attack and stroke), beginning after 18 months of rofecoxib therapy. In patients taking rofecoxib, versus placebo, the relative risk of these events was 1.92 (rofecoxib 1.50 events vs placebo 0.78 events per 100 patient years). The results from the first 18 months of the APPROVe study did not show an increased relative risk of adverse cardiovascular events. Moreover, overall and cardiovascular mortality rates were similar between the rofecoxib and placebo populations. (Bresalier et al., 2005)

In sum, the APPROVe study suggested that long-term use of rofecoxib resulted in nearly twice the risk of suffering a heart attack or stroke compared to patients receiving a placebo.

Other studies

Pre-approval Phase III clinical trials, like the APPROVe study, showed no increased relative risk of adverse cardiovascular events for the first eighteen months of rofecoxib usage (Merck, 2004). Others have pointed out that "study 090," a pre-approval trial, showed a 3-fold increase in cardiovascular events compared to placebo, a 7-fold increase compared to nabumetone (another [NSAID]), and an 8-fold increase in heart attacks and strokes combined compared to both control groups. Although this was a relatively small study and only the last result was statistically significant, critics have charged that this early finding should have prompted Merck to quickly conduct larger studies of Merck's cardiovascular safety. Merck notes that it had already begun VIGOR at the time Study 090 was completed. Although VIGOR was primarily designed to demonstrate new uses for rofecoxib, it also collected data on adverse cardiovascular outcomes.

Several very large observational studies have also found elevated risk of heart attack from rofecoxib. For example, a recent retrospective study of 113,000 elderly Canadians suggested a borderline statistically significant increased relative risk of heart attacks of 1.24 from Vioxx usage, with a relative risk of 1.73 for higher-dose Vioxx usage. (Levesque, 2005). Another study, using Kaiser Permanente data, found a 1.47 relative risk for low-dose Vioxx usage and 3.58 for high-dose Vioxx usage compared to current use of celecoxib, though the smaller number was not statistically significant, and relative risk compared to other populations was not statistically significant. (Graham, 2005).

Furthermore, a more recent study of 114 randomized trial comprised of 116,000+ participants, published in JAMA, showed that Vioxx uniqued increased risk of renal (kidney) disease, and heart arrhythmia.

Withdrawal

Merck publicly announced its voluntary withdrawal of the drug from the market worldwide on September 30, 2004.

In addition to its own studies, on September 23, 2004 Merck apparently received information about new research by the FDA that supported previous findings of increased risk of heart attack among rofecoxib users (Grassley, 2004). FDA analysts estimated that Vioxx caused between 88,000 and 139,000 heart attacks, 30 to 40 percent of which were probably fatal, in the five years the drug was on the market.

On November 5 the medical journal The Lancet published a meta-analysis of the available studies on the safety of rofecoxib (Jüni et al., 2004). The authors concluded that, owing to the known cardiovascular risk, rofecoxib should have been withdrawn several years earlier. The Lancet published an editorial which condemned both Merck and the FDA for the continued availability of rofecoxib from 2000 until the recall. Merck responded by issuing a rebuttal of the Jüni et al. meta-analysis that noted that Juni omitted several studies that showed no increased cardiovascular risk. (Merck & Co., 2004).

In 2005, advisory panels in both the U.S. and Canada encouraged the return of rofecoxib to the market, stating that rofecoxib's benefits outweighed the risks for some patients. The FDA advisory panel voted 17-15 to allow the drug to return to the market despite being found to increase heart risk. The vote in Canada was 12-1, and the Canadian panel noted that the cardiovascular risks from rofecoxib seemed to be no worse than those from ibuprofen -- though the panel recommended that further study was needed for all NSAIDs to fully understand their risk profiles. Notwithstanding these recommendations, Merck has not returned rofecoxib to the market.

Litigation

As of March 2006, there had been over 10,000 cases and 190 class actions filed against Merck over adverse cardiovascular events associated with rofecoxib and the adequacy of Merck's warnings. The first wrongful death trial, Rogers v. Merck, was scheduled in Alabama in the spring of 2005, but was postponed after Merck argued that the plaintiff had falsified evidence of rofecoxib use.

On August 19, 2005, a jury in Texas voted 10-2 to hold Merck liable for the death of Robert Ernst, a 59-year old man who allegedly died of a rofecoxib-induced heart attack. The plaintiffs' lead attorney was Mark Lanier. Merck argued that the death was due to cardiac arrhythmia, which had not been shown to be associated with rofecoxib use. The jury awarded Carol Ernst, widow of Robert Ernst, $253.4 million in damages. This award will almost certainly be capped at no more than USD$26.1 million because of punitive damages limits under Texas law. As of March 2006, the plaintiff had yet to ask the court to enter a judgment on the verdict; Merck has stated that it will appeal.

On November 3, 2005, Merck won the second case Humeston v. Merck, a personal injury case, in Atlantic City, New Jersey. The plaintiff experienced a mild myocardial infarction and claimed that rofecoxib was responsible, after having taken it for two months. Merck argued that there was no evidence that rofecoxib was the cause of Humeston's injury and that there

is no scientific evidence linking rofecoxib to cardiac events with short durations of use. The jury ruled that Merck had adequately warned doctors and patients of the drug's risk.

The first federal trial on rofecoxib, Plunkett v. Merck, began on November 29, 2005 in Houston, Texas. The trial ended in a hung jury and a mistrial was declared on December 12, 2005. According to the Wall Street Journal, the jury hung by an eight to one majority, favoring the defense. Upon retrial in February 2006 in New Orleans, Louisiana, where the Vioxx multi-district litigation (MDL) is based, a jury found Merck not liable, even though the plaintiffs had the NEJM editor testify as to his objections to the VIGOR study.

On January 30th, 2006, a New Jersey state court dismissed a case brought by Edgar Lee Boyd, who blamed Vioxx for gastiointestinal bleeding that he experienced after taking the drug. The judge said that Boyd failed to prove the drug caused his stomach pain and internal bleeding.

In January 2006, Garza v. Merck began trial in Rio Grande City, Texas. The plaintiff, a 71-year-old smoker with heart disease, had a fatal heart attack three weeks after finishing a one-week sample of rofecoxib. On April 21, 2006 the jury awarded the plaintiff $7 million compensatory and $25 million punitive. The punitive amount will be reduced to under $1 Million.

On April 5th, the judge overseeing the MDL litigation dismissed Diaz v. Merck on request of the plaintiff. Merck attorney Phil Beck said that the decision of the Plaintiff Steering Council – a group of lawyers coordinating federal cases against Merck -- to not support "Mr. Diaz' case reflects the evidence proving that Mr. Diaz's heart attack was not caused in any way by his use of Vioxx for 19 months." Diaz's attorney said the request was made because there were too many documents to go through, although the trial date had already been delayed twice.

Merck successfully defended in Doherty v Merck where a grandmother claimed that the drug had caused her heart attack. The jury in Atlantic City, New Jersey found that Vioxx did not contribute to her heart attack, that Merck acted responsibly in informing the medical community about the benefits and risks of the drug and that the drug company's marketing efforts did not mislead consumers.

In August 2006, a jury found in favor of Merck in the company's first case in California, Grossberg v. Merck. The jury found that Merck was not negligent, that it did not conceal information and that Vioxx did not cause Grossberg's heart attack.

Merck has reserved $970 million to pay for its Vioxx-related legal expenses through 2007.

Merck sales representatives are now being subpoenaed to court over selling Vioxx to doctors- patients are claiming the reps knew of the side effects and are partially responsible for the wrongful deaths.

Political impact of Vioxx litigation in America

The recall and litigation over rofecoxib has provoked debate over drug safety in the United States. Some argue that the U.S. Food and Drug Administration does not do enough to monitor product safety and that the rofecoxib withdrawal is an argument against tort reform. It has also been argued that litigation is an imperfect means of regulation that would

overdeter companies for complying with FDA requirements, and that large awards like that in Ernst would inhibit research and development.

Other COX-2 inhibitors

It is currently unknown whether the increased risk of adverse cardiovascular events is common to all COX-2 inhibitors. Recent studies have demonstrated the increased risk of cardiovascular events associated with the use of celecoxib (Celebrex), valdecoxib (Bextra) and parecoxib (Dynastat). (Solomon et al., 2005; Nussmeier et al., 2005)

Newer and more specific COX-2 inhibitors, including etoricoxib (Arcoxia) and lumiracoxib (Prexige), are currently (circa 2005) undergoing Phase III/IV clinical trials. It is likely that these trials will be extended in order to supply additional evidence of cardiovascular safety.

A recent systematic review of 114 clinical trials, published in JAMA 2006, evalated the adverse renal (kidney) and arrhythmia risks of celecoxib, valdecoxib, parecoxib, lumiracoxib, and etoricoxib.

Regulatory authorities worldwide now require warnings about cardiovascular risk of COX-2 inhibitors still on the market. For example, in 2005, EU regulators required the following changes to the product information and/or packaging of all COX-2 inhibitors (EMEA 2005):

- Contraindications stating that COX-2 inhibitors must not be used in patients with established ischaemic heart disease and/or cerebrovascular disease (stroke), and also in patients with peripheral arterial disease
- Reinforced warnings to healthcare professionals to exercise caution when prescribing COX-2 inhibitors to patients with risk factors for heart disease, such as hypertension, hyperlipidaemia (high cholesterol levels), diabetes and smoking
- Given the association between cardiovascular risk and exposure to COX-2 inhibitors, doctors are advised to use the lowest effective dose for the shortest possible duration of treatment

Miscellaneous

- Rofecoxib was shown to improve premenstrual acne vulgaris in a placebo controlled study.

Opioids

An *opioid* is any agent that binds to opioid receptors, found principally in the central nervous system and gastrointestinal tract. There are four broad classes of opioids: endogenous opioid peptides, produced in the body; opium alkaloids, such as morphine (the prototypical opioid) and codeine; semi-synthetic opioids such as heroin and oxycodone; and fully synthetic opioids such as pethidine and methadone that have structures unrelated to the opium alkaloids.

Although the term opiate is often used as a synonym for opioid, it is more properly limited to the natural opium alkaloids and the semi-synthetics derived from them.

Pharmacology

Opioids bind to specific opioid receptors in the central nervous system and in other tissues. There are at least four major classes of opioid receptors: ¼, º, ´ and possibly Ã. In addition, there are two subtypes of ¼ receptor: ¼1 and ¼2.These are all G-protein coupled receptors acting on GABAergic neurotransmission. The pharmacodynamic response to an opioid depends on which receptor it binds, its affinity for that receptor, and whether the opioid is an agonist or an antagonist. For example, the supraspinal analgesic properties of the opioid agonist morphine are mediated by activation of the ¼***1*** receptor, respiratory depression and physical dependence (dependency) by the ¼***2*** receptor, and sedation and spinal analgesia by the º receptor.

Uses

Clinical use

Opioids have long been used to treat acute pain (such as post-operative pain). They have also found to be invaluable in palliative care to alleviate the severe, chronic, disabling pain

of terminal conditions such as cancer. Very high doses are often required in palliation to improve the patients' terminal quality-of-life.

In recent years there has been an increased use of opioids in the management of non-malignant chronic pain. This trend is still somewhat controversial due to issues of dependence.

As recently as the early 20th century, opioids were administered by doctors to treat severe depression and other psychiatric disorders. The practice was discontinued because of the addictive potential of opioids. In recent decades, researchers have experimented with mixed opioid agonist/antagonists such as buprenorphine for the treatment of depression and other psychiatric disorders, encouraged by the decreased liability toward abuse of and dependence on these compounds, compared with full opioid agonists.

United States

The sole clinical indications for opioids in the US, according to Drug Facts and Comparisons, 2005, are

- Analgesia and anesthesia
- Cough (codeine and hydrocodone only)
- Diarrhea (opium only)
- Anxiety due to shortness of breath (oxymorphone only)
- Detoxification (methadone only)

Opioids are prohibited for psychological relief (with the narrow exception of anxiety due to shortness of breath), despite their extensively reported psychological benefits. The basis for this prohibition is not therapeutic but legal (fear of addiction and diversion). The prohibition allows no exceptions, even in areas where researchers have reported opioids to be especially effective and where the possibility of addiction or diversion is very low — for example, in the treatment of senile dementia, geriatric depression, and psychological distress due to chemotherapy or terminal diagnosis.

Recreational use and abuse

Most opioids produce euphoria in many people when ingested orally, intravenously, subcutaneously, rectally, through the nasal membranes, or when smoked. Recreational use and abuse of opioids usually is motivated by a desire to experience this euphoria, which can easily lead to addiction. Tolerance develops rapidly; a regular user may require significantly higher dosages of the drug to achieve the desired effect.

History

Non-clinical use and off-label clinical use were criminalized in the USA by the Harrison Narcotics Tax Act of 1914, and by other laws worldwide. Since then, nearly all non-clinical use and off-label clinical use of opioids has been rated zero on the scale of approval of nearly every social institution. However, in UK the 1926 report of the Departmental Committee on

Morphine and Heroin Addiction under the Chairmanship of the President of the Royal College of Physicians reasserted medical control and established the "British system" of control — which lasted until the 1960s; in the US the Controlled Substances Act of 1970 markedly relaxed the harshness of the Harrison Act.

Before the twentieth century, institutional approval was often higher, even in Europe and America. In some cultures, approval of opioids was significantly higher than approval of alcohol.

Adverse effects

Opioids are associated with a range of adverse drug reactions - mostly associated with their pharmacological actions at opioid receptors.

Common adverse reactions include: nausea and vomiting, drowsiness, dizziness, headache, orthostatic hypotension, itch, dry mouth, miosis, urinary retention, and constipation. (Rossi, 2005)

Infrequent adverse reactions include: dose-related respiratory depression (see below), confusion, hallucinations, delirium, urticaria, hypothermia, bradycardia/tachycardia, ureteric or biliary spasm, muscle rigidity, myoclonus (with high doses), and flushing (due to histamine release, except fentanyl and remifentanil). (Rossi, 2005).

The most serious adverse reaction associated with opioid use is respiratory depression. This can occur with a single dose. Although tolerance develops rapidly, respiratory depression is the mechanism behind the fatal consequences of overdose.

Chronic use of opioids may result in serious constipation, which may progress to bowel obstruction, fecal impaction, or paralytic ileus. Because these conditions may require surgical intervention, stimulant laxatives are generally given as an adjunct to prevent these complications. Physiological tolerance does not develop with regard to constipation. It should be noted that in some therapeutic regimens (such as those aimed at treating diarrhea), mild constipation is a desired effect and hence laxatives would not be given.

With some individuals, opioid use can result in opioid-induced hyperalgesia, whereby individuals using opioids to relieve pain may paradoxically have more pain as a result of their medication. This phenomenon likely results from changes in NMDA receptors in the dorsal horn of the spinal cord.

Both therapeutic and chronic use of opioids can compromise the function of the immune system. Opioids decrease the proliferation of macrophage progenitor cells and lymphocytes, and affect cell differentiation. (Roy & Loh, 1996) Opioids may also inhibit leukocyte migration.

Overdose

Overdose of an opioid can be fatal. The mechanism occurs through depression of the respiratory drive, resulting in hypoxia and eventually death. Opioid overdose can be rapidly reversed with an opioid antagonist such as naloxone or naltrexone. These competitive antagonists bind to the opioid receptors with higher affinity than agonists but do not activate the receptors. This displaces the agonist, attenuating and/or reversing the agonist effects.

However, the elimination half-life of naloxone can be shorter than that of the opioid itself, so repeat dosing or continuous infusion may be required.

Tolerance, Dependence, Addiction, and Abuse

Tolerance is the tendency of the body to adapt to the presence of opioids; this adaptation makes it necessary to use ever-increasing doses of opioids in order to achieve the same effects. Tolerance is more pronounced for some effects than for others.

Dependence is the tendency of the body to manifest a characteristic and unpleasant withdrawal syndrome if regular doses of opioids are abruptly discontinued after tolerance has developed.

Addiction is a psychological attachment to certain effects of opioids (such as the euphoria that many people experience when the drugs are taken in sufficiently large doses) that drives the user to take the drug despite adverse and maladaptive consequences. Dependency and the unpleasantness of withdrawal can work to maintain addiction, although they do not cause it.

All persons receiving opioids for any reason will develop some degree of tolerance and dependence over time, although recent research suggests that these effects can be reduced by the concominant administration of opioid antagonists. [1][2]. Some people will also develop addiction.

Abuse is the misuse or overuse of opioids; the phenomena of tolerance and dependency, combined with the addictive potential presented by some effects of opioids (such as euphoria), make these drugs prime candidates for drug abuse.

Pyschiatric nomenclature in the DSM-IV defines dependence as addiction. As a result, a diagnosis of dependence does not imply that discontinuance of opioids will necessarily trigger a withdrawal syndrome. The nomenclature is being reconsidered for DSM-V.

Tolerance

Tolerance can be detected within 12-24 hours of the administration of morphine (Rang et al., 2003), and similarly for some other opioid agonists. Tolerance results in the necessity for increasing the dose over time to achieve the desired clinical effect.

Tolerance appears to develop first to the analgesic, sedative, emetic, euphoric and respiratory depressive effects of opioids. The miotic and constipating effects are more resistant to the development of tolerance. (Rang et al., 2003)

Dependence and withdrawal issues

Regular use of an opioid for any reason rapidly induces physical dependence, characterized by a highly unpleasant withdrawal syndrome when the drug is discontinued or rapidly reduced in dosage, or when an antagonist is administered, although recent development promises the possibility of chronic opioid use without tolerance or withdrawal[1][2]. The acute withdrawal syndrome generally consists of signs and symptoms opposite to those of the drug when initially administered: severe dysphoria, anxiety, eye

tearing, a runny nose, goose bumps, sweating, nausea, vomiting, cramps and deep pains are common. The speed and severity of withdrawal depends on the half-life of the opioid—heroin withdrawal occurs more quickly and is more severe than methadone withdrawal, but methadone withdrawal takes longer. The acute withdrawal phase is often followed by a protracted phase of depression and insomnia that can last for months.

Physical dependence is distinct from and does not imply psychological addiction, defined as uncontrolled drug use despite harm. However, physical dependence can aggravate psychological addiction when it occurs.

Some patients with narcotic dependence experience recurrent episodes of severe abdominal pain and nausea leading to hospitalizations and extensive diagnostic workups over periods of months to years. The intractable nausea resolves when the pain is treated with narcotics, the patient is able to go home, but another episode recurs when the pain medication runs out.

Withdrawal symptoms can be minimised by slowly tapering the dose over days or weeks, sometimes after switching to a long-acting opioid such as methadone. The symptoms of opioid withdrawal can also be treated with other medications, such as clonidine for sympathetic hyperactivity and a benzodiazepine for anxiety and insomnia.

"Rapid detox" is a relatively new technique that uses opioid antagonists to cause acute withdrawal while the patient is under general anesthesia to eliminate the otherwise extreme discomfort. This procedure has attracted controversy due to its high cost and risk; several patients have died during the procedure. Many pain specialists think that the procedure is unnecessary, and addiction specialists criticize it for doing nothing to keep an addict from relapsing into opioid abuse after the procedure is complete. Indeed, there have been reports of addicts undergoing rapid detox with the full intention of resuming addiction as the technique drastically reduces tolerance thus reducing the cost of addiction. Rapid detox also does not alleviate the protracted withdrawal syndrome that lasts for weeks or months after the acute phase.

Examples of opioids

Endogenous opioids

Opioid-peptides that are produced in the body:

- Endorphins
  - Dynorphins

Enkephalins

Dynorphin Acts through º-opioid receptors, and is widely distributed in the CNS, including in the spinal cord and hypothalamus, including in particular the arcuate nucleus and in both oxytocin and vasopressin neurons in the supraoptic nucleus.

[met]-enkephalin is widely distributed in the CNS;[met]-enkephalin is a product of the proenkephalin gene, and acts through ¼ and ´-opioid receptors.

[leu]-enkephalin , also a product of the proenkephalin gene, acts through ´-opioid receptors

Nociceptin, formerly known as orphanin FQ, is an opioid-related peptide, but it does not act at the classic opioid receptors and actions are not antagonised by the opioid antagonist naloxone. Nociceptin is a potent anti-analgesic. Noiceptin is widely distributed in the CNS; it is found in many regions of the hypothalamus, brainstem, forebrain, as well as in the ventral and dorsal horns of the spinal cord. Nociceptin acts at the NOP1 receptor, formerly known as ORL-1. The receptor is also widely distributed in the brain, including in the cortex, anterior olfactory nucleus, lateral septum, hypothalamus, hippocampus, amygdala, central gray, pontine nuclei, interpeduncular nucleus, substantia nigra, raphe complex, locus coeruleus, and spinal cord.

Endomorphin. Acts through ¼-opioid receptors, and is more potent than other endogenous opioids at these receptors.

²-endorphin is expressed in POMC cells in the arcuate nucleus and in a small population of neurons in the brainstem, and acts through ¼-opioid receptors. ²-endorphin has many effects, including on sexual behavior and appetite.²-endorphin is also secreted into the circulation from pituitary corticotropes and melanotropes. ±-neoendorphin is also expressed in POMC cells in the arcuate nucleus

Opium alkaloids

Phenanthrenes naturally occurring in opium:

- Morphine
- Codeine
- Thebaine

Preparations of mixed opium alkaloids, including papaveretum, are still occasionally used.

Semisynthetic derivatives

- Diacetylmorphine (heroin)
- Oxycodone
- Hydrocodone

Dihydrocodeine
Hydromorphone
Oxymorphone
Nicomorphine

Synthetic opioids

Phenylheptylamines

- Methadone
    - Levo-alphacetylmethadol (LAAM)

Piperanilides

- Fentanyl
    - Alfentanil
    Sufentanil
    Remifentanil
    Ketobemidone
    Carfentanyl
    Ohmefentanyl

Phenylpiperidines

- Pethidine (meperidine)
- Ketobemidone
MPPP
Allylprodine
Prodine
PEPAP

Diphenylpropylamine derivatives

- Propoxyphene
- Dextropropoxyphene
    - Dextromoramide
    Bezitramide
    Piritramide

Benzomorphan derivatives

- Pentazocine
Phenazocine

Oripavine derivatives

- Buprenorphine

Morphinan derivatives

- Butorphanol
Nalbufine
Levorphanol
Levomethorphan

Others

- Dezocine
Etorphine
Lefetamine
Tilidine

- Tramadol

- Loperamide (used for diarrhoea, does not cross the blood-brain barrier)
- Diphenoxylate (used for diarrhoea, does not appreciably cross the blood-brain barrier)

Opioid antagonists

- Naloxone
Naltrexone

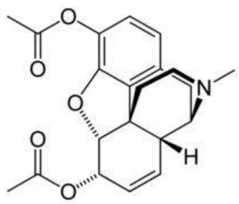
Mu-opioid agonists

Heroin | Morphine

Heroin



Systematic (IUPAC) name

(5±,6±)-7,8-didehydro-4,5-epoxy-
17-methylmorphinan-3,6-diol diacetate (ester)

Identifiers

CAS number 561-27-3

ATC code N02**AA09**

PubChem 3592

Chemical data

Formula $C_{21}H_{23}NO_5$

Mol. weight 369.41

Pharmacokinetic data

Bioavailability <35%

Protein binding 0% (morphine metabolite 35%)

Metabolism hepatic

Half life 2-3 minutes

Excretion 90% renal as glucuronides, rest biliary

Therapeutic considerations

Legal status Schedule I(CA) Class A(UK) Schedule I(US)

Dependence Liability Extremely High

Routes Inhalation, Transmucosal, Intravenous, Oral, Intranasal, Rectal, Intramuscular

Heroin, also known as *diamorphine* (BAN) or *diacetylmorphine* (INN), is a semi-synthetic opioid. It is the 3,6-diacetyl derivative of morphine (hence diacetylmorphine) and is synthesised from it by acetylation. The white crystalline form is commonly the hydrochloride salt, *diacetylmorphine hydrochloride*. It has a high addiction potential, and frequent administration may cause a rapid development of tolerance by the user, especially when compared to other substances, though occasional use may not lead to symptoms of withdrawal.[1][2] Internationally, heroin is controlled under Schedules I and IV of the Single Convention on Narcotic Drugs.[3] It is illegal to manufacture, possess, or sell heroin in the United States; however, under the name *diamorphine*, heroin is a legal prescription drug in the United Kingdom. Popular street names for heroin include gear, diesel, smack, B, skag, Bobby, black tar, horse, junk, jenny, brown, brown sugar, dark, Dope and H.

History

The opium poppy was cultivated in lower Mesopotamia as long ago as 3400 BC.[4] Heroin was first synthesized in 1874 by C.R. Alder Wright, a British chemist working at St. Mary's Hospital Medical School, London. He had been experimenting with combining morphine with various acids. He boiled anhydrous morphine alkaloid with acetic anhydride over a stove for several hours and produced a more potent, acetylated form of morphine, now called diacetylmorphine. The compound was sent to F.M. Pierce of Owens College, Manchester, for analysis, who reported the following to Wright:

Doses ... were subcutaneously injected into young dogs and rabbits ... with the following general results ... great prostration, fear, and sleepiness speedily following the administration, the eyes being sensitive, and pupils dilated, considerable salivation being produced in dogs, and slight tendency to vomiting in some cases, but no actual emesis. Respiration was at first quickened, but subsequently reduced, and the heart's action was diminished, and rendered irregular. Marked want of coordinating power over the muscular movements, and loss of power in the pelvis and hind limbs, together with a diminution of temperature in the rectum of about 4°(rectal failure).[5]

Felix Hoffmann, of Bayer in Elberfeld, Germany, created heroin as a medicine 11 days after inventing aspirin. Afraid of the possible side effects of aspirin, Bayer registered heroin (probably from heroisch, German for heroic, chosen because in field studies people using the medicine felt "heroic") as a trademark.

From 1898 through to 1910 it was marketed as a non-addictive morphine substitute and cough medicine for children. Bayer marketed heroin as a "cure" for morphine addiction before it was discovered that heroin is converted to morphine in the liver. All opiates are converted by the human liver into the identical molecule with varying degrees of concentration in the blood stream. The company felt somewhat embarrassed by this new finding and it became a historical blunder for Bayer.[6] As with aspirin, Bayer lost some of its trademark rights to heroin following World War I.

In the United States in 1914 the Harrison Narcotics Tax Act was passed to control the sale and distribution of heroin. The law still allowed heroin to be prescribed and sold for medical purposes. In particular, addicts could often still be legally supplied with heroin. In 1924, the United States Congress passed additional legislation banning the sale, importation or manufacture of heroin in the United States.

Usage and effects

Indicated for:

Relief of extreme pain
Recreational uses:
Euphoria
Relaxation
Other uses:
Pain relief
Cough suppressant
anti-diarrheal
Contraindications:

Alcohol

Barbiturates and Benzodiazepines

Stimulants

Other opioids (depends heavily on tolerance)

Side effects:

Severe:

Respiratory arrest, seizure, coma, death
Spontaneous abortion
Cardiovascular & Respiratory:
Lowered heart rate
Slowed, shallow or ineffective respiration
Eyes, Ears, nose, and mouth:
Dry mouth
Pupil constriction
Gastrointestinal:
Nausea
Vomiting (protracted)
Constipation
Urinary System:
Urinary retention
Musculoskeletal:

Analgesia

Ataxia
Neurological:

Analgesia

Physical dependence
Psychological:

Anxiolytic

Confusion
Euphoria
Somnolence
Addiction
Skin:
Itching
Flushing/Rash

In the United Kingdom, heroin is available on prescription, though it is a restricted Class A drug. According to the British National Formulary (BNF) edition 50, diamorphine hydrochloride may be used in the treatment of acute pain, myocardial infarction, acute pulmonary edema, and chronic pain. The treatment of chronic non-malignant pain must be supervised by a specialist. The BNF notes that all opioid analgesics cause dependence and tolerance but that this is "no deterrent in the control of pain in terminal illness". When used in the palliative care of cancer patients, heroin is often injected using a syringe driver. In comparison to morphine, it may cause less nausea, hypotension, but more sedation and euphoria and can be dissolved in a smaller quantity of liquid.

Heroin is also widely and illegally used as a powerful and addictive drug that produces intense euphoria, which often disappears with increasing tolerance. It is thought that heroin's popularity with recreational users, compared to morphine or other opiates, comes from its somewhat different perceived effects.[7] This in turn comes from its high lipid solubility provided by the two acetyl groups, resulting in a very rapid penetration of the blood-brain barrier after use. Heroin can be taken or administered in a number of ways, including snorting and injection. It may also be smoked by inhaling the vapors produced when heated from below (known as "chasing the dragon").

Many users in the United Kingdom dissolve the drug together with crack cocaine in a so-called "speedball" or "snowball", which is injected intravenously. This causes an even more intense rush but is more dangerous than heroin alone because the mixture of short-acting stimulant with longer-acting depressant increases the risk of overdosing on one or both drugs. Cocaine is an irritant to all bodily tissues causing eventual necrosis at any site with which it is in frequent contact. Because crack must be acidified with extra citric acid or vitamin C to allow it to dissolve in water, worse vein damage may result than from injecting heroin alone.

Once in the brain, heroin is rapidly metabolized into morphine by removal of the acetyl groups. It is the morphine molecule that then binds with opioid receptors and produces the subjective effects of the heroin high. Heroin is therefore a prodrug.

The onset of heroin's effects is dependent on the method of administration. Orally, the heroin is totally metabolized in vivo into morphine before crossing the blood-brain barrier, so the effects are the same as morphine when taken by mouth. Snorting heroin results in

onset within 10 to 15 minutes. Smoking heroin results in an almost immediate, though mild effect which strengthens the longer it is used in that particular session. Intravenous injection results in rush and euphoria within 7 to 8 seconds, while intramuscular injection takes longer, having an effect within 5 to 8 minutes.

Heroin is a ¼-opioid (mu-opioid) agonist. It acts on endogenous ¼-opioid receptors that are spread in discrete packets throughout the brain, spinal cord and gut in almost all mammals. Heroin, along with other opioids, are agonists to four endogenous neurotransmitters. They are ^{2}-endorphin, dynorphin, leu-enkephalin, and met-enkephalin. The body responds to heroin in the brain by reducing (and sometimes stopping) production of the endogenous opioids when heroin is present. Endorphins are regularly released in the brain and nerves and attenuate pain. Their other functions are still obscure, but are probably related to the effects produced by heroin besides analgesia (antitussin, anti-diarrheal). The reduced endorphin production in heroin users creates a dependence on the heroin, and the cessation of heroin results in extremely uncomfortable symptoms including pain (even in the absence of physical trauma). This set of symptoms is called withdrawal syndrome. It has an onset 6 to 8 hours after the last dose of heroin.

Production and trafficking

Manufacturing

Heroin is produced for the black market through opium refinement processes. Unlike drugs such as LSD, the production of which requires considerable expertise in chemistry and access to constituents which are now tightly controlled, the refinement of the first three grades of heroin from opium is a relatively simple process requiring only moderate technical expertise and common chemicals. The final grade of heroin favored in the west is more difficult to produce and involves a potentially dangerous chemical procedure.

First, morphine is isolated from crude opium by being dissolved in water, reacted with lime fertilizer such that it (morphine) precipitates out, and then reacted again with ammonia. What remains is then mechanically filtered to yield a final product of morphine weighing about 90% less than the original quantity of opium. The morphine is reacted with acetic anhydride — a chemical also used in the production of aspirin — in the complicated five-step process used by most refineries in the Golden Triangle. The first step is to cook the morphine at 85°C (185°F) for six hours with an equivalent weight of acetic anhydride. In the second, a treatment of water and hydrochloric acid then purifies the product moderately. When the chemists add sodium carbonate, the particulates settle. Step four involves heating the heroin in a mixture of alcohol and activated charcoal until the alcohol evaporates. The fifth step is optional, as it only changes the heroin into a finer white powder, more easily injectable; this so-called "no. 4 heroin" is principally exported to the Western markets. In this last, most dangerous step, the heroin (after being dissolved in alcohol), precipitates out in tiny white flakes when a mixture of ether and hydrochloric acid is injected; this step is dangerous due to the fact that the ether may explode, leveling or severely damaging the refinery (as has happened to a number of such facilities).

The purity of the extracted morphine determines in large part the quality of the resulting heroin. Most black market heroin is highly impure due to contaminants left after refinement of opium into morphine which then remain in the final product; even if the final product is in the upper range of purity (80–99% pure), once it reaches the consumer, it typically has been cut multiple times.

History of heroin traffic

The origins of the present international illegal heroin trade can be traced back to laws passed in many countries in the early 1900s that closely regulated the production and sale of opium and its derivatives including heroin. At first, heroin flowed from countries where it was still legal into countries where it was no longer legal. By the mid-1920s, heroin production had been made illegal in many parts of the world. An illegal trade developed at that time between heroin labs in China (mostly in Shanghai and Tientsin) and other nations. The weakness of government in China and conditions of civil war enabled heroin production to take root there. Chinese triad gangs eventually came to play a major role in the heroin trade.

Heroin trafficking was virtually eliminated in the U.S. during World War II due to temporary trade disruptions caused by the war. Japan's war with China had cut the normal distribution routes for heroin and the war had generally disrupted the movement of opium. After the second world war, the Mafia took advantage of the weakness of the postwar Italian government and set up heroin labs in Sicily. The Mafia took advantage of Sicily's location along the historic route opium took from Iran westward into Europe and the United States. Large scale international heroin production effectively ended in China with the victory of the communists in the civil war in the late 1940s. The elimination of Chinese production happened at the same time that Sicily's role in the trade developed.

Although it remained legal in some countries until after World War II, health risks, addiction, and widespread abuse led most western countries to declare heroin a controlled substance by the latter half of the 20th century.

Between the end of World War II and the 1970s, much of the opium consumed in the west was grown in Iran, but in the late 1960s, under pressure from the U.S. and the United Nations, Iran engaged in anti-opium policies. While opium production never ended in Iran, the decline in production in those countries led to the development of a major new cultivation base in the so-called "Golden Triangle" region in South East Asia. In 1970-71, high-grade heroin laboratories opened in the Golden Triangle. This changed the dynamics of the heroin trade by expanding and decentralizing the trade. Opium production also increased in Afghanistan due to the efforts of Turkey and Iran to reduce production in their respective countries. Lebanon, a traditional opium supplier, also increased its role in the trade during years of civil war.

After the overthrow of the Shah of Iran, the new Iranian regime was much more tolerant of opium production. At the same time, the Soviet-Afghan war led to increased production in the Pakistani-Afghani border regions. Both events led to increased international production of heroin at lower prices in the 1980s. The trade shifted away from Sicily in the late 1970s as various criminal organizations violently fought with each other over the trade. The

fighting also led to a stepped up government law enforcement presence in Sicily. All of this combined to greatly diminish the role of the country in the international heroin trade.

Dr Alfred W. McCoy's account of the history of the heroin trade

Although it was beginning to become more prevalent by the 1930s, Asian historian and drug traffic expert Dr Alfred W. McCoy reports that heroin trafficking was virtually eliminated in the U.S. during World War II due to temporary trade disruptions caused by the war. McCoy contends the Mafia was able to gain control of the heroin trade thanks in large measure due to the unintended consequences of a covert deal between top Mafia leader Lucky Luciano and American military intelligence. The deal resulted in a large increase in Mafia influence in Sicily after the 1943 American invasion.

In southeast Asia, the governments of most countries and many colonial officials had been involved in the opium trade for a very long time. Thanks to Corsican Mafia connections in the former French colony of Vietnam, Luciano was able to begin to develop Southeast Asia as a new source of Opium even as Iranian production declined. The Vietnam War and CIA operations in Laos had the unintended consequence of first opening up many areas of Southeast Asia to modern transportation and then presenting a ready-made market for the drug among the U.S. military personnel stationed in the region.

The turning point came in 1970-71 when the first high-grade heroin laboratories opened in the Golden Triangle. Prior to this, the chemical skills for refinement had existed only in Europe. This gave the opium producers control over the creation of the final product. The hundreds of thousands of American servicemen in Vietnam provided a perfect market for the heroin producers, and heroin use among soldiers rapidly increased. In 1971 the first large consignments of South East Asian heroin were intercepted in Europe and America, and by the mid-1970s heroin addiction fulfilled its promise as a serious social problem in the United States, Australia, the United Kingdom, and many other nations.

Trafficking

See also: Opium production

Traffic is heavy worldwide, with the biggest producer being Afghanistan. [8] According to U.N. sponsored survey,[9] as of 2004, Afghanistan accounted for production of 87 percent of the world's heroin.[10] Opium production in that country has increased rapidly since, reaching an all-time high in 2006. War once again appeared as a facilitator of the trade.[11]

Dr. Alfred W. McCoy has claimed that the C.I.A. secretly collaborated with Asian drug syndicates and was complicit in the expansion of the global heroin trade from 1970 to 1973 in order to prosecute the Cold War. While the Vietnam War brought modern transportation to remote opium areas, McCoy himself does not claim that the CIA set up the drug labs in Southeast Asia or created the trade.

Heroin is one of the most profitable illicit drugs since it is compact and easily concealed. At present, opium poppies are mostly grown in the Middle East, Pakistan, and Afghanistan, and in Asia, especially in the region known as the Golden Triangle straddling Myanmar,

Thailand, Vietnam, Laos and Yunnan province in the People's Republic of China. There is also cultivation of opium poppies in the Sinaloa region of Mexico and in Colombia. The majority of the heroin consumed in the United States comes from Mexico and Colombia. Up until 2004, Pakistan was considered one of the biggest opium-growing countries. However, the efforts of Pakistan's Anti-Narcotics Force have since reduced the opium growing area by 59% as of 2001. Some suggest that the decline in Pakistani production is inversely proportional to the rise of Afghani production, and that rather than anti-narcotics activity, the decline in Pakistan is due more to changed market forces.

Conviction for trafficking in heroin carries the death penalty in most Southeast Asia and some East Asia, southern Asia and Middle East countries (see Use of death penalty worldwide for details), among which Malaysia, Singapore and Thailand are the most strict. The penalty applies even to citizens of countries where the penalty is not in place, sometimes causing controversy when foreign visitors are arrested for trafficking, for example the arrest of nine Australians in Bali or the hanging of Australian citizen Van Tuong Nguyen in Singapore, both in 2005.

Risks of non-medical use

- Overdose, possibly causing death

For intravenous users of heroin, the use of non-sterile needles and syringes and other related equipment leads to the risk of contracting blood-borne pathogens such as HIV and hepatitis, as well as the risk of contracting bacterial or fungal endocarditis and possibly Venous sclerosis

Poisoning from contaminants added to "cut" or dilute heroin

Chronic constipation

Heroin-induced leukoencephalopathy (very rare, smokers only)

Many countries and local governments have begun funding programs that supply sterile needles to people who inject illegal drugs in an attempt to reduce these contingent risks and especially the contraction and spread of blood-borne diseases. The Drug Policy Alliance reports that up to 75% of new AIDS cases among women and children are directly or indirectly a consequence of drug use by injection. But despite the immediate public health benefit of needle exchanges, some see such programs as tacit acceptance of illicit drug use. The United States does not support needle exchanges federally by law, and although some state and local governments do support needle exchange programs, they continue to face harassment by police in most areas. Needle exchanges have been instrumental in arresting the spread of HIV/AIDS in many communities with a significant heroin using population, Australia being a leader due to its early inception of needle exchanges. Needle exchange programs have also been attributed to saving the public significant amounts of tax dollars by preventing medical costs which would have been required otherwise for the treatment of diseases spread through the practice of sharing and reusing needles.

A heroin overdose is usually treated with an opioid antagonist, such as naloxone (Narcan) or naltrexone, which have a high affinity for opioid receptors but do not activate them. This blocks heroin and other opioid agonists and causes an immediate return of consciousness and the beginning of withdrawal symptoms when administered intravenously. The half-life of these antagonists is usually much shorter than that of the opiate drugs they are used to

block, so the antagonist usually has to be re-administered multiple times until the opiate has been metabolized by the body.

Depending on drug interactions and numerous other factors, death from overdose can take anywhere from several seconds to several hours. An overdose is immediately reversible with an opioid antagonist injection. Heroin overdoses can occur due to an unexpected increase in the dose or purity or due to diminished opiate tolerance. However, many fatalities reported as overdoses are probably caused by interactions with other depressant drugs like alcohol or benzodiazepines.[12]

The LD***50*** for a person already addicted is prohibitively high, to the point that there is no general medical consensus on where to place it. Several studies done in the 1920s gave addicts doses of 1,600–1,800 mg of heroin in one sitting, and no adverse effects were reported. This is approximately 160–180 times a normal recreational dose. Even for a non-addict, the LD***50*** can be credibly placed above 350 mg.

Street heroin is of widely varying and unpredictable purity. This means that an addict may prepare what they consider to be a moderate dose while actually taking far more than intended. Also, relapsing addicts after a period of abstinence have tolerances below what they were during active addiction. If a dose comparable to their previous use is taken an overdose often results.

A final source of overdose in addicts comes from place conditioning. Heroin use, like other drug abuse behaviors, is highly ritualized. While the mechanism has yet to be clearly elucidated, it has been shown that longtime heroin users, immediately before injecting in a common area for heroin use, show an acute increase in metabolism and a surge in the concentration of opiate-metabolizing enzymes. This acute increase, a reaction to a location where the addict has repeatedly injected heroin, imbues the addict with a strong (but temporary) tolerance to the toxic effects of the drug. When the addict injects in a different location, this place-conditioned tolerance does not occur, giving the addict a much lower-than-expected ability to metabolize the drug. The user's typical dose of the drug, in the face of decreased tolerance, becomes far too high and can be toxic, leading to overdose.[1]

A small percentage of heroin smokers may develop symptoms of leukoencephalopathy. This is believed to be caused by an uncommon adulterant that is only active when heated. Symptoms include slurred speech and difficulty walking. Contrary to popular rumor, aluminum foil probably has nothing to do with the development of leukoencephalopathy in heroin users.

Withdrawal

The withdrawal syndrome from heroin may begin starting from within 6 to 24 hours of discontinuation of sustained use of the drug; however, this time frame can fluctuate with the degree of tolerance as well as the amount of the last consumed dose. Symptoms may include: sweating, malaise, anxiety, depression, persistent and intense penile erection in males (priapism), extra sensitivity of the genitals in females, general feeling of heaviness, cramp-like pains in the limbs, yawning and lacrimation, sleep difficulties, cold sweats, chills, severe muscle and bone aches not precipitated by any physical trauma, nausea and vomiting, diarrhea, goose bumps, cramps, and fever. Many addicts also complain of a painful condition, the so-called "itchy blood", which often results in compulsive scratching that causes bruises

and sometimes ruptures the skin leaving scabs. Abrupt termination of heroin use causes muscle spasms in the legs of the user (restless leg syndrome). Users taking the "cold turkey" approach (withdrawal without using symptom-reducing or counteractive drugs) are more likely to experience the negative effects of withdrawal in a more pronounced manner.

Two general approaches are available to facilitate the physical part of opioid withdrawal. The first is to substitute a longer-acting opioid such as methadone or buprenorphine for heroin or another short-acting opioid and then slowly taper the dose.

In the second approach, benzodiazepines such as diazepam (Valium) may temporarily ease the often extreme anxiety of opioid withdrawal. The most common benzodiazepine employed as part of the detox protocol in these situations is oxazepam (Serax). Benzodiazepine use must be prescribed with care because benzodiazepines have a great addiction potential, and many opioid addicts also use other central nervous system depressants including benzodiazepines and sometimes even the obsolete barbiturates. Also, though unpleasant, opioid withdrawal seldom has the potential to be fatal, whereas complications related to withdrawal from benzodiazepines, barbiturates and alcohol (such as epileptic seizures, cardiac arrest, and delirium tremens) can prove hazardous and potentially fatal. Many symptoms of opioid withdrawal are due to rebound hyperactivity of the sympathetic nervous system, which can be suppressed with clonidine (Catapres), a centrally-acting alpha-2 agonist primarily used to treat hypertension.

Buprenorphine is one of the substances most recently licensed for the substitution of illegal opioids. Being a partial opioid agonist/antagonist, it develops a lower grade of tolerance than heroin or methadone due to the so-called ceiling effect. It also has less severe withdrawal symptoms than heroin when discontinued abruptly, which should never be done without proper medical supervision. It is usually administered every 24-48 hrs. Buprenorphine is a kappa-opioid receptor antagonist. This gives the drug an anti-depressant effect, increasing physical and intellectual activity. Buprenorphine also acts as a partial agonist at the same ¼-receptor where illicit opioids like heroin exhibit their action. Due to its effects on this receptor, all patients whose tolerance is above a certain level are unable to obtain any "high" from other opioids during buprenorphine treatment except for very high doses.

Researchers at Johns Hopkins University have been testing a sustained-release "depot" form of buprenorphine that can relieve cravings and withdrawal symptoms for up to six weeks.[13] A sustained-release formulation would allow for easier administration and adherence to treatment, and reduce the risk of diversion or misuse.

Methadone is another ¼-opioid agonist most often used to substitute for heroin in treatment for heroin addiction. Compared to heroin, methadone is well (but slowly) absorbed by the gastrointestinal tract and has a much longer duration of action of approximately 24 hours. Thus methadone maintenance avoids the rapid cycling between intoxication and withdrawal associated with heroin addiction. In this way, methadone has shown some success as a "less harmful substitute"; despite bearing about the same addiction potential as heroin, it is recommended for those who have repeatedly failed to complete withdrawal or have recently relapsed. As of 2005, the ¼-opioid agonist buprenorphine is also being used to manage heroin addiction, being a superior, though still imperfect and not yet widely known alternative to methadone. Methadone, since it is longer-acting, produces withdrawal symptoms that appear later than with heroin, but usually last considerably

longer and can in some cases be more intense. Methadone withdrawal symptoms can potentially persist for over a month, compared to heroin where significant physical symptoms would subside by 4 days.

Two opioid antagonists are known: naloxone and the longer-acting naltrexone. These two medications block the effects of heroin, as well as the other opioids at the receptor site. Recent studies have suggested that the addition of naloxone and naltrexone may improve the success rate in treatment programs when combined with the traditional therapy.

The University of Chicago undertook preliminary development of a heroin vaccine in monkeys during the 1970s, but it was abandoned. There were two main reasons for this. Firstly, when immunised monkeys had an increase in dose of x16, their antibodies became saturated and the monkey had the same effect from heroin as non-immunised monkeys. Secondly, until they reached the x16 point immunised monkeys would substitute other drugs to get a heroin-like effect. These factors suggested that immunised human addicts would simply either take massive quantities of heroin, or switch to other hard drugs, which is known as cross-tolerance.

There is also a controversial treatment for heroin addiction based on a plant-derived African psychedelic drug, ibogaine. Many people travel abroad for ibogaine treatments that generally interrupt the addiction for 3 - 6 months or more in up to 80% of patients. Relapse often occurs when the person returns home to their normal environment however, where drug seeking behaviour may return in response to social and environmental cues. Ibogaine treatments are carried out in several countries in South America and in Europe but can be dangerous. Some addicts find the ibogaine therapy most effective when it is given several times over the course of a few months or years, but this can be very expensive. A synthetic derivative of ibogaine, 18-methoxycoronaridine is in phase 2 trials in humans as an anti-addictive drug.

Heroin prescription

In 1994 Switzerland began a trial program featuring a heroin prescription for addicts not well suited for withdrawal programs—e.g. those that had failed multiple withdrawal programs. The aim is maintaining the health of the addict in order to avoid medical problems stemming from low-quality street heroin. Reducing drug-related crime was another goal. Addicts can more easily get or maintain a paid job through the program as well. The first trial in 1994 began with 340 addicts and it was later expanded to 1000 after medical and social studies suggested its continuation. Participants are prescribed to inject heroin in specially designed pharmacies for about US $13 per dose.[14]

The success of the Swiss trials led German, Dutch,[15] and Canadian[16] cities to trial their own heroin prescription programs.[17] Some Australian cities (such as Sydney) have trialed legal heroin injecting rooms, in line with other wider harm minimisation programs. Heroin is unavailable on prescription however, and remains illegal outside the injecting room, and effectively decriminilised inside of the injecting room. [citation needed]

Drug interactions

Opioids are strong central nervous system depressants, but regular users develop physiological tolerance allowing gradually increased dosages. In combination with other central nervous system depressants, heroin may still kill even experienced users, particularly if their tolerance to the drug has reduced or the strength of their usual dose has increased.

Toxicology studies of heroin-related deaths reveal frequent involvement of other central nervous system depressants, including alcohol, benzodiazepines such as diazepam (valium), and, to a rising degree, methadone. Ironically, benzodiazepines are often used in the treatment of heroin addiction while they cause much more severe withdrawal symptomes.

Cocaine also proves to be often fatal when used in combination with heroin. Though "speedballs" (when injected) or "moonrocks" (when smoked) are a popular mix of the two drugs among users, combinations of stimulants and depressants can have unpredictable and sometimes fatal results. In the United States in early 2006, a rash of deaths was attributed to either a combination of fentanyl and heroin, or pure fentanyl masquerading as heroin particularly in the Detroit Metro Area; one news report refers to the combination as 'laced heroin', though this is likely a generic rather than a specific term.[18]

Culture

Heroin has inspired countless writers, musicians and other artists over the past century of use. However, its influence is often misunderstood or unfairly assumed; many creative people have used or been addicted to heroin, but the extent to which the drug affected their creativity is debatable. Relatively few artists with great talent have credited heroin use with major epiphanies.

PubChem 5288826

DrugBank APRD00215

Chemical data

Formula $C_{17}H_{19}NO_3$

Mol. weight 285.4

Pharmacokinetic data

Bioavailability **~30%**

Protein binding 30–40%

Metabolism Hepatic 90%

Half life 2–3 hours

Excretion Renal 90%, biliary 10%

Therapeutic considerations

Pregnancy cat. $C_{(AU)}$ $C_{(US)}$

Legal status S8(AU) Schedule I(CA) Class A(UK) Schedule II(US) Prescription only

Dependence Liability Extremely High

Routes smoked/inhaled, insufflated, Oral, SC, IM, IV

Morphine (INN) (IPA: [ÈmT(y)fin]) is an extremely powerful opiate analgesic drug and is the principal active agent in opium. Like other opioids, e.g. heroin, morphine acts directly on the central nervous system (CNS) to relieve pain, and at synapses of the arcuate nucleus, in particular. Side effects include impairment of mental performance, euphoria, drowsiness, lethargy, and blurred vision. It also decreases hunger, inhibits the cough reflex, and produces constipation. Morphine is highly addictive when compared to other substances, and tolerance and physical and psychological dependence develop quickly. Patients on morphine often report insomnia, visual hallucinations and nightmares. Used in ACS "Chest Pain believed to be of cardiac origin" as an adjunct to nitroglycerine providing pain relief, decreasing patient anxiety and minimal coronary artery dilation, which helps oxygenate the heart.

The word "morphine" is derived from Morpheus, the god of dreams in Greek mythology. He is the son of Somnus, god of sleep.

Medical use

Administration

Parenterally as subcutaneous, intravenous, or epidural injections. When injected, particularly intravenously, morphine produces an intense contraction sensation in the muscles and thus produces a powerful 'rush'. The military sometimes issues morphine loaded in an autoinjector.

Orally, it comes as an elixir, concentrated solution, powder (for compounding) or in tablet form. Morphine is rarely supplied in suppository form. Due to its poor oral bioavailability, oral morphine is only one-sixth to one-third of the potency of parenteral morphine. Morphine is available in extended-release capsules for chronic administration, as well as immediate-release formulations.

Uses

Morphine is used legally:

- analgesic in hospital settings for
  - Pain after surgery
  - Pain associated with trauma
- In the relief of severe chronic pain
  - Cancer pain
  - Pain from kidney stones
  - Back pain
- As an adjunct to general anesthesia
- In epidural anesthesia
- For palliative care (i.e. to alleviate pain without curing the underlying reason for it)
- As an antitussive for severe cough
- As an antidiarrheal in chronic conditions (e.g., for diarrhea associated with AIDS)

Contraindications

- acute respiratory depression

acute alcoholism
acute pancreatitis (this may be a result of morphine use as well)
renal failure (due to accumulation of the metabolite morphine-6-glucuronide)

Pharmacology

Indicated for:

Relief of extreme pain

Recreational uses:
Euphoria
Relaxation
Other uses:
Pain relief
Cough suppressant
anti-diarrheal
Contraindications:

Alcohol

Barbiturates and Benzodiazepines

Stimulants

Other opioids (depends heavily on tolerance)

Side effects:

Severe:

Respiratory arrest
Spontaneous abortion
Cardiovascular:
Lowered heart rate
Ear, nose, and throat:
Dry mouth
Endocrinal:
Eugonadism
Eye:
Pupil constriction
Intermittent blurring
Gastrointestinal:
Nausea
Constipation
Hepatological:

- none

Neurological:

Analgesia

Psychological:

Anxiolysis

Confusion
Euphoria
Sedation
Respiratory:
Slow and shallow respiration
Skin:
Itchiness
Flushing

Morphine is an phenanthrene opioid receptor agonist – its main effect is binding to and activating the μ-opioid receptors in the central nervous system. Activation of these receptors is associated with analgesia, sedation, euphoria, physical dependence and respiratory depression. Morphine is also a º-opioid receptor agonist, with this action associated with spinal analgesia and miosis.

Like loperamide and other opioids, morphine acts on the myenteric plexus in the intestinal tract reduce gut motility, leading to constipation.

The effects of morphine can be countered with naloxone or naltrexone.

Morphine is primarily metabolized into morphine-3-glucuronide and morphine-6-glucuronide. Morphine-6-glucuronide (M6G) has been found to be a far more potent analgesic than morphine when dosed to rodents. M6G has also been found to be analgesic in humans. The significance of M6G formation on the observed effect of a dose of morphine is the subject of extensive debate among pharmacologists.

High doses of morphine may be fatal due to respiratory depression. Nevertheless, patients in extreme pain are able to tolerate very high doses of morphine. This is because pain stimulates respiration, thus counteracting the respiratory depression.

Legal classification

- In the United Kingdom, morphine is listed as a Class A drug under the Misuse of Drugs Act 1971.
- In the United States, morphine is classified as a Schedule II drug under the Controlled Substances Act.
- In Australia, morphine is classified as a Schedule 8 drug under the Therapeutic Goods Act 1989 (2003).[1]
- Internationally, morphine is a Schedule I drug under the Single Convention on Narcotic Drugs[2].

History and abuse

Morphine was first isolated in 1804 by the German pharmacist Friedrich Wilhelm Adam Sertürner (or Barnard Courtois), who named it "morphium" after Morpheus, the Greek god of dreams. But it was not until the development of the hypodermic needle (1853) that its use spread. It was used for pain relief, and as a "cure" for opium and alcohol addiction. Its extensive use during the American Civil War allegedly resulted in over 400,000 sufferers from the "soldier's disease" of morphine addiction, although critics believe this to be a highly

erroneous and misleading claim, pointing to the glaring lack of documented post-war cases[3].

Heroin (diacetylmorphine) was derived from morphine in 1874. As with other drugs, its possession without a prescription was criminalized in the U.S. by the Harrison Narcotics Tax Act of 1914.

Morphine is routinely carried by soldiers on operations in an autoinjector.

Morphine was the most commonly abused narcotic analgesic in the world up until heroin was synthesized and came into use. Even today, morphine is one of the most sought after prescription narcotics by heroin addicts when heroin is scarce.

In a randomised double-blind study with crossover at an outpatient clinic in Bern, Switzerland, morphine was proven to have stronger side-effects than heroin at equianalgesic doses. Respiratory depression, miosis, sedation, itchiness, and euphoria were more pronounced with morphine.

Natural opium alkaloids

The term *opiate* refers to the alkaloids found in opium, an extract from the seed pods of the opium poppy (Papaver somniferum L.). It has also traditionally referred to natural and semi-synthetic derivatives of morphine. The term is often incorrectly used to refer to all drugs with opium- or morphine-like pharmacological action, which are more properly classified under the broader term opioid.

The main opiates derived from opium are morphine, codeine and thebaine. Papaverine and noscapine are also present, but have essentially no effect on the central nervous system, and are not usually considered to be opioids. Papaveretum is a standardised preparation of mixed opium alkaloids used on cardiac patients.

Routes oral, intra-nasally, intra-rectally, SC, IM

Codeine (INN) or *methylmorphine* is an opiate used for its analgesic, antitussive and antidiarrheal properties. It is marketed as the salts *codeine sulfate* and *codeine phosphate*. *Codeine hydrochloride* is more commonly marketed in continental Europe and other regions.

Codeine is an alkaloid found in opium in concentrations ranging from 0.3 to 3.0 percent. While codeine can be extracted from opium, most codeine is synthesized from morphine through the process of O-methylation.

Indications

Approved indications for codeine include:

- Cough, though its efficacy has been disputed.[1]
- Diarrhea
- Moderate to severe pain

Codeine is sometimes marketed in combination preparations with paracetamol (acetaminophen) as co-codamol (best known as Tylenol 3), with aspirin co-codaprin or with ibuprofen. These combinations provide greater pain relief than either agent used alone (q.v. Drug Synergy).

Controlled substance

In the United States, codeine is regulated by the Controlled Substances Act. It is a Schedule II controlled substance for pain-relief products containing codeine alone. In combination with aspirin or acetaminophen (paracetamol/tylenol) it is listed as Schedule III. Codeine is also available outside the United States as an over-the-counter drug in liquid cough-relief formulations. Internationally, codeine is a Schedule II drug under the Single Convention on Narcotic Drugs.[2]

In the United Kingdom, codeine is regulated by the Misuse of Drugs Act 1971; it is a Class B drug, except for concentrations of less than 8 mg when combined with paracetamol, or 12.5 mg when combined with ibuprofen, which are available in many over the counter preparations.

In Australia, New Zealand and Canada, codeine is regulated; however, it is available without prescription in combination preparations from licensed pharmacists in doses up to 15 mg/tablet (8 mg/tablet in Canada).

In Canada, codeine can only be sold in combination with 2 or more ingredients, which has resulted in the prevalence of AC&C (aspirin, codeine, and caffeine), and similar combinations using acetaminophen rather than asprin. Caffeine, being a stimulant, tends to offset the sedative effects of codeine.

Pharmacokinetics

Codeine is considered a prodrug, since it is metabolised in vivo to the principal active analgesic agent morphine. It is, however, less potent than morphine since only about 10% of the codeine is converted. It also has a correspondingly lower dependence-liability than morphine.

Theoretically, a dose of approximately 200 mg (oral) of codeine must be administered to give equivalent analgesia to 30 mg (oral) of morphine (Rossi, 2004). It is not used, however, in single doses of greater than 60mg (and no more than 240 mg in 24 hours) since there is a ceiling effect.

The conversion of codeine to morphine occurs in the liver and is catalysed by the cytochrome P450 enzyme CYP2D6. Approximately 6–10% of the Caucasian population have poorly functional CYP2D6 and codeine is virtually ineffective for analgesia in these patients (Rossi, 2004). Many of the adverse effects, however, are still experienced. Also, some medications are CYP2D6 inhibitors and reduce or even completely eliminate the efficacy of codeine. The most notorious of these are the selective serotonin reuptake inhibitors, such as fluoxetine (Prozac) and citalopram (Celexa).

Pharmacology

Codeine itself has weak affinity for the ¼-opioid receptor. Its principal analgesic actions are mediated by the affinity of morphine for the ¼-opioid receptor, though other therapeutic and adverse effects are produced by activation of other opioid receptors.

Adverse effects

Common adverse drug reactions associated with the use of codeine include itching, nausea, vomiting, drowsiness, dry mouth, miosis, orthostatic hypotension, urinary retention and constipation.[3]

Tolerance to many of the effects of codeine develops with prolonged use, including therapeutic effects. The rate at which this occurs develops at different rates for different effects, with tolerance to the constipation-inducing effects developing particularly slowly for instance.

A potentially serious adverse drug reaction, as with other opioids, is respiratory depression. This depression is dose-related and is the mechanism for the potentially fatal consequences of overdose.

Another side effect commonly noticed is the lack of sexual drive. It is generally due to lethargy caused by abuse of codeine.

Codeine has also been known to interact negatively with some psychiatric medications such as reboxetine and venlafaxine.

Recreational use

Codeine is often used as a recreational drug. This may be due to its easy availability over the counter or on prescription in combination products (which, in certain countries, are scheduled lower than codeine as a single-agent). People use it in order to obtain the euphoric effects associated with use of opioids. Codeine-containing cough syrups are often taken whole by drinking the syrup; combination pills may be taken whole or crushed and insufflated (snorted), or the codeine may be extracted using methods like cold water extraction.

- In certain areas of the United States, such as Texas, codeine in syrup form is called Lean. It is commonly mixed with alcohol, or into a joint (marijuana cigarette) and smoked.
- When prepared with promethazine, codeine is a Schedule V controlled substance in the United States. In a few states, such as New Jersey, codeine with promethazine is available over the counter. The syrup, sometimes known as Phenergan With Codeine, contains 6.25 mg of promethazine and 10 mg of codeine per teaspoonful.
- In some countries, cough syrups and tablets containing codeine are available without prescription; people will frequently purchase it from multiple pharmacies so as not to incur suspicion. It is reported that in France, 95% of the consumption of Néo-codion cough preparation, containing codeine, cannot be attributed to medical use, but is rather used as a substitute for heroin. A heroin addict may use codeine to ward off the effects of a withdrawal.[4]
- In the United Kingdom, people purchase tablets which combine codeine and paracetamol (acetaminophen), and consume these at higher-than-recommended doses, without apparent concern of the hepatotoxicity associated with large doses of paracetamol. Some try to extract the codeine from the

paracetamol through various methods, the most common and simplest being the cold water extraction.

- While the combination of codeine with paracetamol at higher-than-recommended doses can possibly cause hepatotoxicity (liver damage), combination with ibuprofen can result in kidney problems/failure and additional stomach pain and nausea, and combination with aspirin can lead to internal hemorrhaging, particularly gastrointestinal hemorrhage.
- In South Asian countries codeine has become a multi-million-dollar market in the form of codeine-phosphate-containing cough syrups which are easily available at chemist shops without a prescription, notable among them being Corex and Phensydryl. Although it is nominally mandatory to have a prescription, it is a highly neglected rule, especially in smaller cities where prescriptions are ignored on a regular basis. Codeine phosphate tablets are also available over the counter, despite being prescription-only as well. They are among the most abused over-the-counter drugs in South Asia (across all sections of its society), and continue to be freely available despite legislations by States to curb their availability to buyers without prescriptions.
- Certain codeine products are encountered on the illicit market, frequently in combination with carisoprodol. Combinations of codeine and glutethimide (Doriden) used to be fairly commonplace, but are almost unheard of today, due to the withdrawal of glutethimide products from the marketplace in the US and almost all other countries.
- Codeine is also demethylated to illicitly synthesize morphine.[5]

Routes Oral, intravenous, intramuscular, rectal,[5] intracavernosal

Papaverine is an opium alkaloid used primarily in the treatment of visceral spasm, vasospasm (especially those involving the heart and the brain), and occasionally in the treatment of erectile dysfunction[3]. While it is found in the opium poppy, papaverine differs in both structure and pharmacological action from the other opium alkaloids.

Uses

Papaverine is approved to treat spasms of the gastointestinal tract, bile ducts and ureter and for use as a cerebral and coronary vasodilator[3] in subarachnoid hemorrhage (combined with balloon angioplasty)[6] and coronary artery bypass surgery[7]. Papaverine may also be used as a smooth muscle relaxant in microsurgery where it is applied directly to blood vessels.

The in vivo mechanism of action is not entirely clear, but an inhibition of the enzyme phosphodiesterase causing elevation of cyclic AMP levels is significant. It may also alter mitochondrial respiration.

Side effects

Frequent side effects of papaverine treatment include polymorphic ventricular tachycardia, constipation, interference with sulphobromophthalein[8] retention test (used to determine hepatic function), increased transaminase levels, increased alkaline phosphatase levels, hyperbilirubinemia, somnolence, and vertigo[3].

Rare side effects include flushing of the face, hyperhidrosis (excessive sweating), cutaneous eruption, arterial hypotension, tachycardia, lack of appetite, jaundice, eosinophilia, thrombopenia, mixed hepatitis, headache, allergic reaction, chronic active hepatitis,[3] and paradoxical aggravation of cerebral vasospasm[9].

Formulations and Tradenames

Papaverine is available as a conjugate of hydrochloride, codecarboxylate, adenylate, and teprosylate[10]. It was also once available as a salt of hydrobromide, camsylate, cromesilate, nicotinate, and phenylglycolate. The hydrochloride salt is available for intramuscular, intravenous, rectal and oral administration.[5] The teprosylate is available in intravenous, intramuscular, and orally administered formulations[11]. The codecarboxylate is available in oral form, only,[12] as is the adenylate[13].

The codecarboxylate is sold under the name Albatran®,[14] the adenylate as Dicertan®,[15] and the hydrochloride salt is sold variously as Artegodan® (Germany), Cardioverina® (countries outside Europe and the United States), Dispamil® (countries outside Europe and the United States), Opdensit® (Germany), Panergon® (Germany), Paverina Houde® (Italy, Belgium), Pavacap (United States), Pavadyl® (United States), Papaverin-Hamelin® (Germany), Paveron® (Germany), Spasmo-Nit® (Germany),[5] Cardiospan®, Papaversan®, Cepaverin®, Cerespan®, Drapavel®, Forpaven®, Papalease®,

Pavatest®, Paverolan®, Therapav® (France[16]), Vasospan®, Cerebid®, Delapav®, Dilaves®, Durapav®, Dynovas®, Optenyl®, Pameion®, Papacon®, Pavabid®, Pavacen®, Pavakey®, Pavased®, Pavnell®, Alapav®, Myobid®, Vasal®, Pamelon®, Pavadel®, Pavagen®, Ro-Papav®, Vaso-Pav®, Papanerin-hcl®, Qua bid®, Papital T.R.®, Paptial T.R.®, Pap-Kaps-150®.[17]

Half life 3 - 4.5 hours

Excretion Urine

Therapeutic considerations

Pregnancy cat. B/D(prolonged use or in high doses at term)

Legal status Schedule I(CA) Class A(UK) Schedule II(US)

Dependence Liability Moderate - High

Routes Oral, intramuscular, intravenous, intranasally, subcutaneous, transdermal, rectal

Oxycodone is a potent and addictive opioid analgesic medication synthesized from thebaine. Its name is derived from codeine - the chemical structures are very similar, differing only in that the hydrogen on the codeine is oxidised to a hydroxyl group, hence 'oxy' and the hydroxyl group from the codeine becomes a ketone group, hence 'oxycodone.'

It is effective orally and is marketed in combination with acetylsalicylic acid (*Percodan*, *Endodan*, *Roxiprin*) or paracetamol/acetaminophen (*Percocet*, *Endocet*, *Roxicet*, *Tylox*) for the relief of pain. More recently, ibuprofen has been added to oxycodone (*Combunox*). It is also sold in a sustained-release form by Purdue Pharma under the trade name *OxyContin* as well as generic equivalents, and instant-release forms *Endone*, *OxyIR*, *OxyNorm*, *Percolone*, *OxyFAST*, and *Roxicodone*. Roxicodone is available in 5, 15, and 30 mg tablets. OxyContin is available in 10, 20, 40, 80, and 160 mg tablets, and, due to its sustained-release mechanism, is effective for eight to twelve hours. Outside the U.S. OxyContin is also available in a 5 mg tablet. (The 160 mg formulation was discontinued in May 2001.) OxyNorm is available in 5, 10, and 20 mg capsules and tablets; also as a 1 mg/1 ml liquid in 250 mg bottles and as a 10 mg/1 ml concentrated liquid in 100 mg bottles.

In the United States, oxycodone is a Schedule II controlled substance both as a single agent and in combination products containing paracetamol, ibuprofen or aspirin.

Chemical structure

The chemical structure of oxycodone is the methylether of oxymorphone: 3-Methyl-oxymorphone. It could also be described as 14-Hydroxy-Codeinone. It is principally supplied as its hydrochloride salt: oxycodone hydrochloride

Bioavailability

Oxycodone can be administered orally, intranasally, via intravenous/intramuscular/subcutaneous injection, or rectally. The bioavailability of intranasal administration averages between 46-47%, but can be as much as 75%. Oral oxycodone is the most efficient means of administration, having an absorbtion of 60-87%.

Rectal administration yields the same results. Injecting oxycodone will result in a stronger effect, and quicker onset, with a bioavailability slightly higher than oral administration.[1]

Medical use

Oxycodone is one of the most powerful medications for pain control that can be taken orally. Percocet tablets (Oxycodone with acetaminophen) are routinely prescribed for post-operative pain control. Oxycodone is also used in treatment of moderate to severe chronic pain. When used at recommended doses for relatively short periods (several weeks), it provides effective pain control with manageable side effects. Both immediate release oxycodone and sustained-release OxyContin are prescribed for pain due to cancer more than for any other condition. Due to an increase in cranial pressure, though clinically negligible, oxycodone is rarely recommended as a first-line treatment for medical issues of the head, including accidents involving brain trauma or spinal meningitis infections.

Nausea, constipation, lightheadedness, rash or itchiness, dizziness, and emotional mood disorders are the most frequently reported side effects. Other side-effects can also include slightly decreased testosterone levels in men. Misuse or long-term medical use of the drug can cause temporary impotence as well as a significant prostate enlargement in men.

Tolerance and physical dependence occurs after several days to weeks of treatment, with larger doses being required to achieve the same degree of analgesia.

According to the DEA and the companies that manufacture the drug, psychological addiction as a result of medical use is uncommon. Despite this statement, there are several lawsuits underway brought by plaintiffs who claim to have developed addiction as a result of medical use.

Several companies such as Elite Pharmaceuticals, Inc. and Pain Therapeutics, Inc are currently developing an anti-abuse version of oxycodone. Elite's ELI-216 has completed Phase I clinical trials and Pain Therapeutics' new drug called Remoxy is in Phase III clinical trials.

History

Oxycodone is an agonist opioid, and as such is a variation on an ancient theme beginning with the simple consumption or smoking of the alkaloid-bearing parts of Papaver somniferum, the opium poppy, first cultivated circa 3400 BC in lower Mesopotamia. Ancient Sumerians, Assyrians, Babylonians, and Egyptians found that smoking the extract derived from the seedpods yielded a pleasurable, peaceful feeling throughout the body. The Sumerians called the poppy plant "Hul Gil" or "joy plant". Cultivation and use spread quickly to the rest of the Levant and the Arabian Peninsula, eventually reaching India and China.

Oxycodone is a semi-synthetic opioid derived from the alkaloid thebaine, unlike most early opium-derived drugs which instead used the morphine or codeine alkaloids also found in the plant. Oxycodone was first synthesized in a German laboratory in 1916, a few years after the German pharmaceutical company Bayer had stopped the mass production of heroin due to addiction and abuse by both patients and physicians. It was hoped that a thebaine-derived drug would retain the analgesic effects of morphine and heroin with less of the euphoric effect which led to addiction and over-use. To some extent this was achieved, as oxycodone does not "hit" the central nervous system with the same immediate punch as heroin or morphine do and it does not last as long. The subjective experience of a "high" was

still reported for oxycodone, however, and it made its way into medical usage in small increments in most Western countries until the introduction of the OxyContin preparation radically boosted oxycodone use.

Abuse

The introduction of OxyContin in 1995 resulted in increasing patterns of abuse. Unlike Percocet, whose potential for abuse is limited by the presence of paracetamol, OxyContin contains only oxycodone and inert filler. Abusers wash off the coating and crush the tablets to defeat the time-release mechanism, then either ingest the resulting powder orally, intranasally, via intravenous/intramuscular/subcutaneous injection, or rectally to achieve rapid absorption into the bloodstream. Injection of OxyContin is particularly dangerous since it contains binders which enable the time release of the drug. Often mistaken as the time release, the outside coating of the pill is merely used as a color code for different dosage amounts. The vast majority of OxyContin-related deaths are attributed to ingesting substantial quantities of oxycodone in combination with another depressant of the central nervous system such as alcohol or benzodiazepines. While high doses of oxycodone can be fatal to an opiate-naïve individual in and of itself, this is (comparatively) rarely the case. It was once felt that "combination" opioids (those that contain one or more additional, non-narcotic ingredients) would be less subject to abuse, since, for example, the amount of paracetamol present in large overdoses of Percocet would cause stomach upset and liver damage. However, it has been demonstrated that abusers seeking the euphoric "high" are not deterred by these potential side effects or toxicities. Abusers soon discovered that extremely simple methods to separate the ingredients exist, particularly due to the widely disparate solubility of the alkaloids and analgesics in water ("cold water extraction").

Oxycodone has similar effects to morphine and heroin, and appeals to the same abuse community. Armed robberies of pharmacies where the robber demanded only OxyContin, not cash, have occurred. In some areas, particularly the eastern U.S., OxyContin has been the drug of greatest concern to enforcement authorities, although trustworthy data on the actual incidence of "Oxy abuse" have been difficult to establish.

Because oxycodone is highly regulated, when acquired illegally it is quite expensive. Black market prices in Washington, DC, and Portland, Maine, for example, have been reported to reach upwards of one dollar per milligram. In parts of Kentucky, particularly in Appalachia, nearly $1.25/mg. Legally acquired OxyContin is however rather expensive, costing as much as 400 US dollars for a normal month supply. Again, in mid-2006, brand-name or similar-quality generic (e.g., Watson, Purdue) eighty-milligram tablets sold for approximately twelve dollars whereas low-end generics (e.g., the above-referenced "footballs") scarcely pushed three dollars.

In Australia OxyContin is covered by the PBS, and a patient can get 3 boxes (60 tablets) for $4.70AUD in total. This has led to Federal tightening of restrictions from May 2006 (see Regulation below). The 20mg tablet can fetch $30AUD-$50AUD on the Gold Coast black market. As such there are professional "Doctor shoppers" making a tidy profit each week from OxyContin.

Like other opioids, oxycodone can be fatal at high doses or when combined with depressants such as alcohol. Several documented fatalities from OxyContin abuse have been

made public; however, these have done little to deter the combined use of the drug with depressants on account of the intense euphoria it produces.

In early 2006 on the East Coast there were multiple antectodal reports of "fake" OxyContin 80mg tablets, especially in Philadelphia and New York City. These fake OxyContin consistly mainly of sugar and were of poor quality, noting the distinct green color which differs from commercially made tablets. There have also been multiple reports of fake OxyContin 80mg tablets that contained Fentanyl.[2]

Conservative radio host Rush Limbaugh is a famous admitted former OxyContin addict and abuser[3]. Jason Mewes was also addicted to OxyContin whilst also abusing heroin until he became clean.

Illegal distribution of OxyContin occurs through pharmacy diversion, dishonest physicians, "doctor shopping," fake prescriptions, and robbery, all of which divert the pharmaceutical onto the illicit market. The increase of this situation coincides with the increase in the illegal use and abuse of this drug. The oxycodone contained in OxyContin produces opiate-like effects, and is considered a "reasonable substitute" for heroin[4]. The most commonly diverted dosages are the 40mg and 80mg strengths[4].

Manufacturer and Patents

OxyContin was first introduced onto the market by Purdue Pharma L.P. in 1995. This pharmaceutical company was founded in 1892 in New York City, and is currently a privately owned company that operates solely within the United States. The different branches within this company include, Purdue Pharma L.P., The Purdue Frederick Company, Purdue Pharmaceutical Products L.P., and Purdue Products L.P. (www.pharma.com). It has multiple patents for their drug OxyContin, but has recently been involved in a series of on going legal battles deciding on whether or not these patents are valid. On June 7th, 2005, the United States Court of Appeals upheld a decision from the previous year that some of Purdue's patents for OxyContin could not be enforced. This decision allowed and led to the immediate announcement from Endo Pharmaceutical Holdings, Inc. that they would begin launching a generic version of all four strengths of OxyContin[5]. Purdue, however, had already made negotiations with another pharmaceutical company (IVAX Pharmaceuticals) to distribute their brand OxyContin in a generic form. This contract was severed, and currently Watson Pharmaceuticals is the exclusive U.S. distributor of the generic versions of OxyContin Tablets. The agreement stipulates that "Purdue will manufacture and supply oxycodone HCI controlled-release tablets to Watson, which will market, sell, and distribute the authorized generic product in 10, 20, 40, and 80 milligram dosages in the United States"[6].

Purdue Pharma L.P. is based out of Stamford, Connecticut, and is the site of the company's headquarters. Manufacturing takes place at three different sites, which include: Purdue Pharmaceuticals L.P., a plant located in Wilson, North Carolina, The P.F. Laboratories Inc. in Totowa, New Jersey, and Rhodes Technologies L.P. located in Coventry, Rhode Island. Purdue Pharma L.P. also has research labs located in Cranbury, New Jersey. OxyContin is currently legally and illegally distributed throughout the U.S., Canada, and Mexico. Legal distribution takes place from the P.F. Laboratories Inc. in Totowa. Since the drug is a controlled substance, a prescription is required to obtain it, and is shown to be most frequently prescribed in the eastern U.S.[4]. Purdue also exports OxyContin to wholesale distributors in Mexico and

Canada. However, they have experienced increasing levels of illicit drug trafficking with the distribution outside of the U.S. that has led to certain responsive actions. The pill exported to Mexico is stamped with the letters "EX" instead of the customary "OC," and similarly the pills to Canada read "CDN." Purdue stopped exporting to Canada in 2001, and instead Canada imports the drug from a manufacturer in England. Despite these problems, OxyContin is one of the leading opioid painkillers on the market. In 2001, OxyContin was the highest sold drug of its kind, and in 2000, over 6.5 million prescriptions were written[7].

Chemistry

Oxycodone is made, commercially, from thebaine, a minor component of opium. The 14 hydroxy group increases potency by about 50% over hydrocodone. The 14 cinnamyl ester is 114x morphine in potency.

Regulation

Regulation of oxycodone (and opioids in general) differs according to country, with different places focusing on different parts of the "supply chain".

Regulation in the USA

Regulation of prescription drugs comes from many different areas. The Food and Drug Administration (FDA) approves drugs for medical use, as well as sets regulations for the marketing of drugs, including controlled substances. The Drug Enforcement Administration (DEA) on the other hand, receives its regulatory authority from the Controlled Substances Act (CSA) [21 U.S.C. §§ 801-971], which "mandates that DEA prevent, detect and investigate the diversion of legally manufactured controlled substances while, at the same time, ensuring that there are adequate supplies to meet the legitimate medical needs in the United States"[8].

Part of the regulation of prescription drugs is connected to their marketing and advertising. The FDA has authority over this sector under the Food, Drug, and Cosmetic (FD&C) Act and its implementing regulations. The Division of Drug Marketing, Advertising, and Communications (DDMAC) is "responsible for regulating prescription drug advertising and promotion," and has a "mission is to protect the public health by ensuring that prescription drug information is truthful, balanced, and accurately communicated"[9].

Regulation in Australia

In contrast, in Australia a General Practitioner can prescribe up to a 10 day supply of OxyContin, provided that they gain authority from Canberra for each prescription written. Prescriptions for a 30 day supply require two doctors, and must be cleared by Canberra. Additional prescriptions (i.e. for chronic pain or cancer patients) require two doctors for the first prescription, one of whom is a Pain Specialist, the treatment must have started within a hospital, and at least one of the prescribing doctors must be a designated as primary

prescriber by a Pain Specialist, and each prescription must be cleared by Canberra. Pharmacists must report the issuing of all oxycodone to the same authority in Canberra - mismatches found between prescribers, patients and Pharmacists result in investigation.

Advertising

Purdue Pharma L.P. does not use direct-to-consumer advertising, but instead focuses their marketing tactics towards health care professionals exclusively. They do this through the use of paper advertisements in medical journals and other publications of this nature, as well as promotion and sale directly to physicians, pharmacies, and hospitals. In January of 1996, Purdue signed a co-promotion agreement with Abbott in regards to their OxyContin Tablets. Abbott is now involved in the promotion of the drug to anesthesiologists and surgeons in hospitals throughout the U.S. (www.pharma.com). Although Purdue does not use direct-to-consumer advertising, OxyContin is becoming an increasingly more publicized and known drug to the general public. The discovery of its recreational benefits has led to an illicit underground market. As discussed earlier, due to acts such as pharmacy diversion and "doctor shopping" the drug is widely available to those without a prescription. The increased misuse of the drug has led to a higher number of emergency department mentions and deaths associated with oxycodone[4]. Despite the increased efforts by the FDA, DEA, and state/local authorities, along with this negative publicity of the drug is not stopping its illicit use, but instead seems to be fueling the underground market.

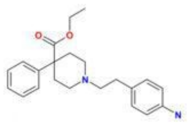
Synthetic opioids - Anileridine



Systematic (IUPAC) name ethyl1-[2-(4-aminophenyl)ethyl]- 4-phenyl-piperidine-4-carboxylate

Identifiers

CAS number 144-14-9

ATC code **N01**AH05

PubChem 8944

DrugBank APRD00741

Chemical data

Formula $C_{22}H_{28}N_2O_2$

Mol. weight 352.47 g/mol

Physical data

Melt. point 83 °C (181 °F)

Pharmacokinetic data

Protein binding > 95%
Anileridine (Leritine) is a synthetic opioid and strong analgesic medication.

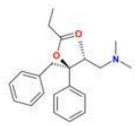
Administration

As tablets or injection.

Pharmacokinetics

Anileridine usually takes effect within 15 minutes of either oral or intravenous administration, and lasts 2-3 hours. It is mostly metabolized by the liver.

Dextropropoxyphene



Systematic (IUPAC) name

[(2R,3R)-4-dimethylamino- 3-methyl-1,2-diphenyl-butan-2-yl] propanoate

Identifiers

ATC code **N02**AC04

PubChem 10100

Chemical data

Formula C22H29NO2

Mol. weight 339.471

Dextropropoxyphene is an analgesic in the opioid category. It is used to treat mild to moderate pain and as an antitussive. It can be used to ease pain before, during and after an operation. It is often combined with acetominophen in the preparation co-proxamol (Darvocet in the US and CAPADEX in AUS).

It is an optical isomer of Levopropoxyphene. The racemic mixture is called Propoxyphene.

Some preparations that contain dextropoxyphene include: Distalgesic and Doloxene.

Indications

Analgesia

Dextropropoxyphene, like codeine, is a "weak" opioid. Codeine is more commonly used, however some individuals (approximately 10-20% of the Caucasian population) are unable to metabolize it, due to poor functioning of the enzyme CYP2D6. It is in these people that dextropropoxyphene is particularly useful, as its metabolism does not require CYP2D6.

Opioid withdrawal

In pure form, dextropropoxyphene is commonly used to ease the withdrawal symptoms in people addicted to opioids. Being very weak in comparison to the opioids that are

commonly abused, dextropropoxyphene can only act as a "partial" substitute. It does not have much effect on mental cravings; however it can be effective in alleviating physical withdrawal effects, such as muscle cramps.

Dextropropoxyphene is subject to some controversy: while many physicians prescribe it for a wide range of mildly to moderately painful symptoms as well as for treatment of diarrhoea, many others refuse to prescribe it, citing its highly addictive nature and limited effectiveness (some studies show it to be no more effective as a painkiller than aspirin).

The therapeutic index of dextroproxyphene is relatively small. In the UK, dextropropoxyphene and co-proxamol are now discouraged from general use; and, since 2004, preparations containing only dextropropoxyphene have been discontinued. This has been a somewhat controversial decision, since it has caused abusers to switch to the combined product and risk acetominophen toxicity. Australia declined to follow suit and opted to allow pure dextropropoxyphene to remain available by prescription.

In the United States, dextropropoxyphene HCl is available as a prescription formulation with acetaminophen in ratio anywhere from 30mg / 600mg to 60mg / 325mg, respectively. These are usually named "Darvocet." On the other hand, "Darvon" is a pure Propoxyphene preparation available in the U.S. that does not contain acetominophen. In Australia, dextropropoxyphene is available on prescription, both as a combined product (32.5mg dextropropoxyphene per 325mg acetaminophen) known as either "Di-gesic", "Capadex", or "Paradex," and in pure form (100mg capsules) known as "Doloxene".

Adverse effects

Darvocet overdose is commonly broken into two categories: liver toxicity (from acetaminophen poisoning) and dextropropoxyphene overdose. Many users experience toxic effects from the acetaminophen in pursuit of the endlessly-increasing dose required to achieve euphoria. They suffer acute liver toxicity, which causes severe stomach pain, nausea, and vomiting (all of which are increased by light or stimulation of the sense of sight).

Dextropropoxyphene also has several other non-opioid side-effects.

Both propoxyphene and it's metabolite norpropoxyphene, have local anesthetic effects at concentrations about 10 times those necessary for opioid effects. In this respect, norpropoxyphene is more potent than propoxyphene, and they are both more potent than lidocaine.[1]

Both propoxyphene and norpropoxyphene also have direct cardiac effects which include decreased heart rate, decreased contractility, and decreased electrical conductivity (ie, increased PR, AH, HV, and QRS intervals). Norpropoxyphene is several times more potent than propoxyphene in this activity. These effects appear to be due to their local anesthetic activity and are not reversed by naloxone.[1][2][3]

Both propoxyphene and norpropoxyphene are potent blockers of cardiac membrane sodium channels and are more potent than lidocaine, quinidine, and procainamide in this respect.[4]

They (propoxyphene and nor-propoxyphene) appear to have the characteristics of a Vaughn Williams Class IC antiarrhythmic.

Toxicologic Mechanism

A) Excessive opioid receptor stimulation is responsible for the CNS depression, respiratory depression, miosis, and gastrointestional effects seen in propoxyphene poisoning. It may also account for mood/thought altering effects.

B) Local anesthetic activity appears to be responsible for the arrhythmias and cardiovascular depression seen in propoxyphene poisoning.[3] Widening of the QRS complex appears to be a result of a quinidine-like effect of propoxyphene, and sodium bicarbonate therapy appears to have a positive direct effect on the QRS dysrhythmia.[5]

C) Seizures may result from either opioid or local anesthetic effects.[1]

D) Pulmonary edema may result from direct pulmonary toxicity, neurogenic/anoxic effects, or cardiovascular depression.[3]

Recreational use

Recreational users tend to take anywhere from 240 to 420 milligrams of dextropropoxyphene (and the acetaminophen that goes with it). These users often suffer a persistent dry mouth, decreased appetite, urinary retention and constipation that may lead to diverticulitis.

Dextropropoxyphen Hydrochloride is also used in the so-called "Darvon cocktail"

Endorphins

Endorphins (or more correctly Endomorphines) are endogenous opioid biochemical compounds. They are peptides produced by the pituitary gland and the hypothalamus in vertebrates, and they resemble the opiates in their abilities to produce analgesia and a sense of well-being. In other words, they might work as "natural pain killers." Using drugs may increase the effects of the endorphins.

The term "endorphin" implies a pharmacological activity (analogous to the activity of the corticosteroid category of biochemicals) as opposed to a specific chemical formulation.

History

These opioid neuropeptides were first discovered in 1975 by two independent groups of investigators. John Hughes and Hans Kosterlitz of Scotland isolated — from the brain of a pig — what they called "enkephalins" (from the Greek µ½ºÆ±»¿Â, cerebrum). Around the same time in the calf brain, Rabi Simantov and Solomon H. Snyder of the United States found what Eric Simon (who independently discovered opioid receptors in the brain) later termed "endorphin" by an abbreviation of "endogenous morphine", which literally means "morphine produced naturally in the body". In fact, morphine itself is not a peptide. However, recent studies have demonstrated that diverse animals and human tissues can produce morphine.

Molecular biology

There are at least three different families of opioid peptides. The endorphins are products of a gene that encodes a large precursor peptide called pro-opiomelanocortin (POMC); POMC is expressed in the pituitary gland and in the arcuate nucleus of the hypothalamus. The best-known endorphins are ±-, ^{2}- and ^{3}-endorphin, of which *^{2}-endorphin* appears to be most implicated in pain relief.

The amino acid residue sequence (primary structure) of ^{2}-endorphin is:

Tyr-Gly-Gly-Phe-Met-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Asn-Ala-Ile-Ile-Lys-Asn-Ala-Tyr-Lys-Lys-Gly-GluOH (Fries, 2002).

Other opioid peptides are the enkephalins and the dynorphins. The term enkephalin mainly refers to two peptides, [Met]-enkephalin and [Leu]-enkephalin, which are both products of the proenkephalin gene. [Met]-enkephalin is Tyr-Gly-Gly-Phe-Met. [Leu]-enkephalin has Leu in place of Met. Dynorphin is the product of a third opioid gene, called prodynorphin.

Mechanism of action

Beta-endorphin is released into the blood (from the pituitary gland) and into the spinal cord and brain from hypothalamic neurons. The beta-endorphin that is released into the blood cannot enter the brain in large quantities because of the blood-brain barrier. The physiological importance of the beta-endorphin that can be measured in the blood is far from clear: beta-endorphin is a cleavage product of POMC which is the precursor hormone for adrenocorticotrophic hormone (ACTH), so it will be released whenever ACTH is released. The behavioural effects of beta-endorphin are exerted by its actions in the brain and spinal cord, and probably the hypothalamic neurons are the major source of beta-endorphin at these sites.

Beta-endorphin has the highest affinity for the Mu1-opioid receptor, slightly lower affinity for the Mu2 and Delta-opioid receptors and low affinity for the Kappa1-opioid receptors. Mu receptors are the main receptor through which morphine acts. Classically, Mu receptors are presynaptic, and inhibit neurotransmitter release; through this mechanism, they inhibit the release of the inhibitory neurotransmitter GABA, and disinhibit the dopamine pathways, causing more dopamine to be released. By hijacking this process, exogenous opioids cause inappropriate dopamine release, and lead to aberrant synaptic plasticity which causes addiction. Opioid receptors have many other and more important roles in the brain and periphery however, modulating pain, cardiac, gastric and vascular function as well as possibly panic and satiation, and receptors are often found at postsynaptic locations as well as presynaptically

Activity

Scientists debate whether specific activities release measurable levels of endorphins. Much of the current data comes from animal models which may not be relevant to humans.

The studies that do involve humans often measure endorphin plasma levels, which do not necessarily correlate with levels in the CNS. Other studies use an opioid antagonist, usually naloxone, to indirectly measure the release of endorphins by observing the changes that occur when any endorphin activity that might be present is blocked.

Capsaicin (the active chemical in chili peppers) also has been shown to stimulate endorphin release. Topical capsaicin has been used as a treatment for certain types of chronic pain.

The placebo effect has been linked to endorphins. In one study, a volunteer received pain by a compression cuff on his arm. In the first trial, no drug was administered and the patient showed signs of pain including facial grimace, increased blood pressure, and sweating. During the next trial, the physician informed the volunteer that he would be injected with morphine and that he would feel no pain. The morphine was injected, the pain compression repeated, and this time the volunteer showed and reported no pain. The morphine and compression was repeated several times. Then, the volunteer was unknowingly injected with a saline placebo, but still reported no sign of pain, though the last time he was unmedicated the signs of pain were obvious. In a last test, the patients' 'morphine' was actually an injection of naloxone, an opioid antagonist. Even though the volunteer believed the shot was morphine and expected relief, the endorphins' effect was blocked by the naloxone injection and the volunteer displayed the same signs of pain as the first unmedicated trial. (Groopman 169)

Another widely publicized effect of endorphin production is the so-called "*runner's high*", which is said to occur when strenuous exercise takes a person over a threshold that activates endorphin production. Endorphins are released during long, continuous workouts, when the level of intensity is between moderate and high, and breathing is difficult. This also corresponds with the time that muscles use up their stored glycogen and begin functioning with only oxygen. Workouts that are most likely to produce endorphins include running, swimming, cross-country skiing, long distance rowing, bicycling, aerobics, or playing a sport such as basketball, soccer, or football. However, some scientists question the mechanisms at work, their research possibly demonstrating the high comes from completing a challenge rather than as a result of exertion. (Klosterman) (Altman) There is some recent evidence that endogenous cannabinoids are responsible for "runner's high", rather than endorphins. (Endocannabinoids and exercise, by A Dietrich and W F McDaniel, May 4, 2004 bjsportsmed.com). Studies in the early 1980's cast doubt on the relationship between endorphins and the runner's high. There were a couple of reasons for this doubt. The first was that when an antagonist (pharmacological agent that blocks the action for the substance under study) was infused (eg naloxone) or ingested (naltrexone) the same changes in mood state occurred that happened when the person exercised with no blocker. A second piece of evidence is much more simple. It turns out that scientists cannot make a runner's high occur in the lab with any certainty. This makes it very difficult to study much less prove that endorphins cause the runners high.

In 1999, clinical researchers reported that inserting acupuncture needles into specific body points triggers the production of endorphins [2]. In another study, higher levels of endorphins were found in cerebrospinal fluid after patients underwent acupuncture. In addition, naloxone appeared to block acupuncture's pain-relieving effects. However, skeptics

say that not all studies point to that conclusion, and that in a trial of chronic pain patients, endorphins did not produce long-lasting relief. (Margolis 140-141).

The good feeling one gets from eating chocolate, smiling, laughing, sunbathing, being massaged, meditating, singing, listening to one's favorite music, or having an orgasm is partially attributed to the release of endorphins. [3]

Half life 7 (range 3-12) hours

Therapeutic considerations

Pregnancy cat. $C_{(US)}$

Legal status Schedule $II_{(US)}$

Routes TD, IM, IV, oral, sublingual, buccal

Fentanyl is an opioid analgesic, first synthesized by Janssen Pharmaceutica (Belgium) in the late 1950s, with an analgesic potency of about 80 times that of morphine. Fentanyl was introduced into medical practice in the 1960s as an intravenous anesthetic under the trade name of Sublimaze. Fentanyl has an LD50 of 3.1 milligrams per kilogram in rats. The LD50 in humans is not known. Fentanyl is a Schedule II drug.

Synthesis

The synthesis of fentanyl (N-phenyl-N-(1-phenethyl-4-piperidinyl)propanamide) by Janssen Pharmaceutica was achieved in four steps, starting from 4-piperidinone hydrochloride. The 4-piperidinone hydrochloride was first reacted with phenethyl bromide to give N-phenethyl-4-piperidinone (NPP). Treatment of the NPP intermediate with aniline followed by reduction with sodium borohydride afforded 4-anilino-N-phenethyl-piperidine (ANPP). A final reaction between ANPP and propionic anhydride led to the fentanyl with a 47% overall yield.

Analogues

The pharmaceutical industry has developed several analogues of fentanyl:

- Alfentanil (Alfenta), an ultra-short acting (5–10 minutes) analgesic,
- Sufentanil (Sufenta), a potent analgesic (5 to 10 times more potent than fentanyl) for use in heart surgery.
- Remifentanil, currently the shortest acting opioid, has the benefit of rapid offset, even after prolonged infusions.
- Carfentanil (Wildnil) is an analogue of fentanyl with an analgesic potency 10,000 times that of morphine and is used in veterinary practice to immobilize certain large animals.

Therapeutic use

All forms of fentanyls are to be used only by opioid-tolerant patients; several deaths have occurred when used by other patients. Today, fentanyls are extensively used for anesthesia and analgesia. Duragesic, by Janssen Pharmaceutica, is a fentanyl transdermal patch used in chronic pain management. Duragesic patches work by releasing fentanyl into subcutaneous fats, which then slowly release the drug into the blood stream over 72 hours, allowing for long lasting relief from pain. In the past few years, the patches have gone generic and are available for lower costs. Duragesic is manufactured in five patch sizes: 12.5 μg/h, 25 μg/h, 50 μg/h, 75 μg/h, and 100 μg/h. Dosage is based on the size of the patch, since the transdermal absorption rate is generally constant at a constant skin temperature. Rate of absorption is dependent on a number of factors. Body temperature, skin type and placement of the patch can have major effects. The different delivery systems used by different makers will also affect individual rates of absorption.

Actiq, by Cephalon, is a recently-developed solid formulation of fentanyl citrate on a stick in the form of a lollipop that dissolves slowly in the mouth for transmucosal absorption. Actiq is intended for opioid-tolerant individuals and is effective in treating breakthrough cancer pain. It is also useful for breakthrough pain for those suffering bone injuries, severe back pain, neuropathy, arthritis, and some other examples of chronic nonmalignant pain. The unit is a berry-flavored lozenge on a stick which is swabbed on the mucosal surfaces inside the mouth—inside of the cheeks, under and on the tongue and gums—to release the fentanyl quickly into the system. It is most effective when the lozenge is consumed in 15 minutes. The drug is less effective if swallowed, absorption from the alimentary tract being poor. Actiq is available in six dosages, from 200 to 1600 μg in 200 μg increments (excluding 1000 μg and 1400 μg). Actiq is now available in the United states in generic form[1], through an FTC consent agreement[2].

FENTORA™ is a new delivery method of fentanyl; it is an effervescent tablet placed in the cheek and is absorbed through the buccal mucosa. It was introduced on 2006-09-25[3]. One advantage of FENTORA is quicker absorption into the bloodstream at lower dosage levels according to the prescribing information[4].

Fentanyl is frequently given intrathecally as part of spinal anesthesia or epidurally for epidural anesthesia and analgesia.

Illicit use

Illicit use of pharmaceutical fentanyls first appeared in the mid-1970s in the medical community and continues in the present. United States authorities classify fentanyl as a narcotic. To date, over 12 different analogues of fentanyl have been produced clandestinely and identified in the U.S. drug traffic. The biological effects of the fentanyls are similar to those of heroin, with the exception that there is less of a euphoric 'high' associated with the drug and a stronger analgesic effect. Additionally, fentanyl may be hundreds of times more potent — though in some places, it is sold as heroin, often leading to overdoses. Fentanyl also has a shorter half-life than that of heroin, and is most commonly used orally, but like heroin, can also be smoked, snorted or injected.

Actiq has appeared on the streets under the street name of "percopop". The pharmacy retail price ranges from US$16 to US$50 per unit (based on strength of lozenge), with the black market cost is anywhere from US$20 to US$60 per unit, depending on the strength.

Some heroin dealers mix fentanyl powder with larger amounts of heroin in order to increase potency or compensate for low-quality heroin, and to increase the volume of their product. As of late May 2006, a mix of fentanyl and either cocaine or heroin has caused an outbreak in overdose deaths in the United States, heavily concentrated in the cities of Detroit, Philadelphia, Milwaukee, Camden, Chicago,[5], and Little Rock. The mixture of fentanyl and heroin is known as "magic", among other names, on the street. [6]

Both Actiq and Duragesic are becoming as popular as OxyContin in pharmacy burglaries and robberies. In the U.S., law enforcement agencies are being instructed in how to tell the difference between Actiq and other medications so they are better able to notice abuse of the drug.

Several large quantities of illicitly-produced fentanyl have been seized by U.S. law enforcement agencies. In June 2006, 945 grams of 83%-pure fentanyl powder were seized by Border Patrol agents in California from a vehicle which had entered from Mexico. Mexico is the source of much of the illicit fentanyl for sale in the U.S. However, there has been one domestic fentanyl lab discovered by law enforcement, in April 2006 in Azusa, CA. The lab was a source of counterfeit 80 mg OxyContin tablets containing fentanyl instead of oxycodone, as well as bulk fentanyl and other drugs.[8],[9]

The "china white" form of fentanyl refers to the clandestinely produced alpha-methyl strain (AMF) [10] . This has been reported in the literature to be twice the strength of regular fentanyl. The main bonus of the alpha-methyl is it provides a site of resistance to metabolic degradation resulting in a drug with an increased duration [11].

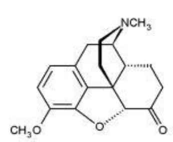
Hydrocodone



Systematic (IUPAC) name

4,5a-Epoxy-3-methoxy-17-methylmorphinan-6-one tartrate (1:1) hydrate (2:5)

Identifiers

CAS number 125-29-1

ATC code R05**DA03**

PubChem 5284569

DrugBank APRD00591

Chemical data

Formula C***18***H***21***NO***3***

Mol. weight 299.368

Pharmacokinetic data

Metabolism Hepatic

Half life 4-8 hours

Therapeutic considerations

Pregnancy cat. Category C (USA)

Legal status Class A (UK), Schedule III (USA)

Routes Oral

Hydrocodone or *dihydrocodeinone* (marketed as *Vicodin*, *Anexsia*, *Dicodid*, *Hycodan*, *Hycomine*, *Lorcet*, *Lortab*, *Norco*, *Novahistex*, *Hydroco*, *Tussionex*, *Vicoprofen*) is a semi-synthetic opioid derived from two of the naturally occurring opiates, codeine and thebaine. Hydrocodone is an orally active narcotic analgesic and antitussive. Sales and production of this drug have increased significantly in recent years, as have diversion and illicit use. Hydrocodone is commonly available in tablet, capsule and syrup form.

Acetaminophen 650mg

As a narcotic, hydrocodone relieves pain by binding to opioid receptors in the brain and spinal cord. It may be taken with or without food. When taken with alcohol, it can intensify drowsiness. It may interact with monoamine oxidase inhibitors, as well as other drugs that cause drowsiness. It is in FDA pregnancy category C: its effect on an embryo or fetus is not clearly known and pregnant women should consult their physicians before taking it. Common side effects include dizziness, lightheadedness, nausea, drowsiness, euphoria, vomiting, and constipation. Some less common side effects are allergic reaction, blood disorders, changes in mood, mental fogginess, anxiety, lethargy, difficulty urinating, spasm of the ureter, irregular or depressed respiration and rash.

Hydrocodone can be habit-forming, and can lead to physical and psychological addiction. In the U.S., pure hydrocodone and forms containing more than 15 mg per dosage unit are considered Schedule II drugs. Those containing less than or equal to 15 mg per dosage unit in combination with acetaminophen or another non-controlled drug are called hydrocodone compounds and are considered Schedule III drugs. Hydrocodone is typically found in combination with other drugs such as paracetamol (acetaminophen), aspirin, ibuprofen and homatropine methylbromide. The purpose of the non-controlled drugs in combination is often twofold. 1) To provide increased analgesia via drug synergy. 2) To limit the intake of hydrocodone by causing unpleasant and often unsafe side effects at higher than prescribed doses (See Below). In the UK it is listed as a Class A drug under the Misuse of Drugs Act 1971.

Overdosing risks

The presence of acetaminophen in hydrocodone-containing products deters many drug users from taking excessive amounts. However, some users will get around this by extracting a portion of the acetaminophen using hot/cold water, taking advantage of the water-soluble element of the drug. It is not uncommon for addicts to have liver problems from consuming excessive amounts of acetaminophen over a long period of time; taking 10,000 to 15,000 milligrams (10 to 15 grams) of acetaminophen in a period of 24 hours typically results in severe hepatotoxicity, and doses in the range of 15,000-20,000 milligrams a day have been reported as fatal.[1] It is this factor that leads many addicts to use only single entity opiates such as OxyContin.

Daily consumption of hydrocodone should not exceed 40 milligrams in patients not tolerant to opiates. However, the 2006 PDR (Physicians Desk Reference) clearly states that Norco 10, containing 10 milligrams of hydrocodone and 325 milligrams of APAP (viz., acetaminophen or paracetamol), can be taken at a dosage of up to twelve tablets per day (120 milligrams of hydrocodone). Such high amounts of hydrocodone are *only* intended for opiate-tolerant patients, and titration to such levels must be monitored very carefully. This restriction is only limited by the fact that twelve tablets, each containing 325 milligrams of APAP, puts the patient right below the 24-hour FDA maximum of 4,000 mg of APAP. Some specially compounded products are routinely given to chronic pain patients in doses of up to 180 mg of hydrocodone per day. Tolerance to this drug can increase very rapidly if abused. Because of this, addicts often overdose from taking handfulls of pills, in pursuit of the high they experienced very early on in their hydrocodone use. Symptoms of hydrocodone overdosage include respiratory depression, extreme somnolence, coma, stupor, cold and/or clammy skin, sometimes bradycardia, and hypotension. A severe overdose may involve circulatory collapse cardiac arrest and/or death.

Alcohol

It is not recommended to mix any amount of hydrocodone with any amount of alcohol as doing so could cause health problems. APAP is metabolized solely by the liver. Therefore the risk of fatal overdose due to hepatotoxicity can occur with significantly lower levels of APAP when mixed with ethanol. This fact is often neither known nor given credence as it does not stop people from mixing them due to the feeling of euphoria it provides.

Commercial medications containing hydrocodone

When sold commercially, hydrocodone often is combined with another medication. Those combined with acetaminophen are known by various trademark names, such as Vicodin and Lortab. Hydrocodone also can be combined with aspirin (e.g., Lortab ASA), ibuprofen (e.g., Vicoprofen), and certain antihistamines (e.g., Chemdal HD).

Below are some of the commercially available medications containing hydrocodone, listed by manufacturer.

Abbott Laboratories

Dosage - Appearance - Trademark Name

5mg (500mg acetaminophen) - White tablets bisected on one side and debossed "VICODIN" on the other side - Vicodin

7.5mg (750mg acetaminophen) - White tablets with tapered edges bisected on one side and debossed "VICODIN ES" on the other side - Vicodin ES

10mg (660mg acetaminophen) - White tablets bisected on one side and debossed "VICODIN HP" on the other side - Vicodin HP

7.5mg (200mg ibuprofen) - Round white tablets debossed on one side with "VP" above the Abbott logo (a stylized, lower case "a") and blank on the other side - Vicoprofen

UCB Pharma

Dosage - Appearance - Trademark Name

2.5mg (500mg acetaminophen) - White tablets with red specs bisected and debossed "901" on one side and debossed "UCB" on the other side - Lortab

5mg (500mg acetaminophen) - White tablets with blue specs bisected and debossed "902" on one side and debossed "UCB" on the other side - Lortab

7.5mg (500mg acetaminophen) - White tablets with green specs bisected and debossed "903" on one side and debossed "UCB" on the other side - Lortab

10mg (500mg acetaminophen) - Pink tablets bisected and debossed "910" on one side and debossed "UCB" on the other side - Lortab

5mg (500mg aspirin) - Red tablets mottled with white and debossed "500" on one side and (possibly?) debossed "UCB" on the other side - Lortab ASA

7.5mg per 15mL (500mg acetaminophen) - Yellow, tropical-punch flavored liquid with 7% alcohol - Lortab Elixir

Watson Pharmaceuticals, Inc.

(NOTE: Watson manufactures under its own Trademarks and generic Trademark Equivalents)

Dosage - Appearance - Trademark Name

10mg (750mg acetaminophen) - Yellow Capule-shaped bisected on one side and debossed "Maxidone 634" on the other side - Maxidone®

5mg (325mg acetaminophen) - White tablets with orange specks bisected and debossed "Watson" on one side and "Watson 913" on the other side - Norco® 5/325

7.5mg (325mg acetaminophen) - Light orange oblong tablets bisected on one side and debossed "NORCO 729" on the other side - Norco® 7.5/325

10mg (325mg acetaminophen) - Yellow tablets bisected on one side and debossed "NORCO 539" on the other side - Norco®

Dosage - Appearance - Trademark Equivalent
2.5mg (500mg acetaminophen) - White tablets bisected on one side and debossed "WATSON 388" on the other side - Lortab®

5mg (325mg acetaminophen) - White tablets with orange specks bisected and debossed "Watson" on one side and "3202" on the other side - Norco® 5/325

5mg (500mg acetaminophen) - White oblong tablets bisected on one side and debossed "WATSON 349" on the other side - Vicodin®

7.5mg (325mg acetaminophen) - Light orange oblong tablets bisected on one side and debossed "WATSON 3203" on the other side - Norco® 7.5/325

7.5mg (500mg acetaminophen) - White tablets bisected on one side and debossed "WATSON 385" on the other side - Lortab®

7.5mg (650mg acetaminophen) - Pink tablets bisected on one side and debossed "WATSON 502" on the other side - Lorcet Plus®

7.5mg (750mg acetaminophen) - White tablets bisected on one side and debossed "WATSON 387" on the other side - Vicodin ES®

10mg (325mg acetaminophen) - Yellow tablets bisected on one side and debossed "WATSON 853" on the other side - Norco®

10mg (500mg acetaminophen) - Blueish/purple tablets bisected on one side and debossed "WATSON 540" on the other. - Lortab®

10mg (650mg acetaminophen) - Light green tablets bisected on one side and debossed "WATSON 503" on the other side - Lorcet 10/650®

10mg (660mg acetaminophen) - White tablets bisected on one side and debossed "WATSON 517" on the other side - Generic

10mg (750mg acetaminophen) - Yellow tablets bisected on one side and debossed "WATSON 3228" on the other side - Maxidone®

Mallinckrodt Pharmaceuticals

Dosage - Appearance - Trademark Name

5mg (325mg acetaminophen) - White tablets bisected on one side and debossed "M365" on the other side - Generic

5mg (500mg acetaminophen) - White tablets bisected on one side and debossed "M357" on the other side - Generic

7.5mg (325mg acetaminophen) - White tablets bisected on one side and debossed "M366" on the other side - Generic

7.5mg (500mg acetaminophen) - White tablets bisected on one side and debossed "M358" on the other side - Generic

7.5mg (650mg acetaminophen) - White tablets bisected on one side and debossed "M359" on the other side - Generic

7.5mg (750mg acetaminophen) - White tablets bisected on one side and debossed "M360" on the other side - Generic

10mg (325mg acetaminophen) - White tablets bisected on one side and debossed "M367" on the other side - Generic

10mg (500mg acetaminophen) - White tablets bisected on one side and debossed "M363" on the other side - Generic

10mg (650mg acetaminophen) - Blue tablets bisected on one side and debossed "M361" on the other side - Generic

10mg (660mg acetaminophen) - White tablets bisected on one side and debossed "M362" on the other side - Generic

10mg (750mg acetaminophen) - White tablets bisected on one side and debossed "M364" on the other side - Generic

Laudanum

Laudanum is an opium tincture, sometimes sweetened with sugar and also called wine of opium.

History

In the 16th century, Paracelsus experimented with the medical value of opium. He decided that its medical (analgesic) value was of such magnitude that he called it Laudanum,

from the Latin laudare, to praise, or from labdanum, the term for a plant extract. He did not know of its addictive properties.

In the 19th century, laudanum was used in many patent medicines to "relieve pain... to produce sleep... to allay irritation... to check excessive secretions... to support the system... [and] as a sudorific". The limited pharmacopoeia of the day meant that opium derivatives were among the most efficacious of available treatments, and so laudanum was widely prescribed for ailments from colds to meningitis to cardiac diseases, in both adults and children.

The Romantic and Victorian eras were marked by the widespread use of laudanum in Europe, and the United States. Initially a working class drug, laudanum was cheaper than a bottle of gin or wine, because it was treated as a medication for legal purposes and not taxed as an alcoholic beverage. Notable addicted literary figures include: Edgar Allan Poe; Samuel Taylor Coleridge, who was addicted for much of his adult life; Thomas de Quincey, who turned his addiction into literary success with the publication of Confessions of an English Opium Eater; Lord Byron; Percy Bysshe Shelley, who suffered raging laudanum-induced hallucinations; John Keats; Iolo Morgannwg, the Welsh antiquarian; Charles Dickens; Antonin Artaud; and Charles Baudelaire[citation needed]. There were also political figures, such as William Wilberforce and Meriwether Lewis, who used the drug.

Innumerable Victorian women were prescribed the drug for relief of menstrual cramps and vague aches and used it to achieve the pallid complexion associated with tuberculosis (frailty and paleness were particularly prized in females at the time). Nurses also spoon-fed laudanum to infants.

Featurings in fiction

In Literature

- In the Aubrey–Maturin series of novels, the ship's surgeon, Stephen Maturin, both uses the drug professionally and battles his own addiction to it.
- In Alan Moore's The League of Extraordinary Gentlemen, Allan Quatermain, opium-addicted, uses his bottle of laudanum to paralyze Edward Hyde.
- In Joanne Harris's 1993 novel Sleep Pale Sister, Effie was fed laudanum to keep her out of "hysterics" and also so that she could sleep.
- The character of Oscar Hopkins in Peter Carey's novel Oscar and Lucinda (1988) uses laudanum, initially under duress, to dull his hydrophobia during his expedition from Sydney.
- Mary Shelley's character Victor Frankenstein uses laudanum to help him sleep after the death of his friend, Henry Clerval.
- In Jack Finney's Time and Again, the main character, Si Morley, wonders if a live baby in a 1882 display case has been "doped up with one of the laudanum preparations I'd seen advertised in Harpers."
- Laudanum is also used as a means to circumvent Speck magic in the Soldier Son Trilogy by Robin Hobb.

- Laudanum is mentioned frequently in William S. Burroughs' Naked Lunch, and The Soft Machine Trilogy.
- In the tenth chapter of James Joyce's Ulysses, Haines is depicted drinking laudanum from a phial **[1]**.
- In Octavia Butler's "Kindred" Rufus' Mother uses laudanum as a medicine to relieve her pain and sorrow
- Laudanum is also mentioned in the song "A Legionnaire's lament" by the Decemberists.
- In Wilkie Collins' "The Moonstone" [1868], a valuable diamond, the Moonstone, is stolen by a character in a laudanum induced stupor.

In Film

- In the 2001 movie From Hell laudanum plays an important role: Jack the Ripper is shown using it to numb his victims while Inspector Frederick Abberline (played by Johnny Depp) is addicted to a laudanum and absinthe mixture.
- In the movie Tombstone, Wyatt Earp's wife is addicted to laudanum.
- In Interview with the Vampire (book and film) Claudia gives a laudanum and absinthe mixture to a small boy, on whom Lestat then feeds and becomes quite weak.
- In John Wayne's final movie The Shootist, his character J.B. Books is suffering from terminal cancer, and his doctor E.W. Hostetler (played by James Stewart) prescribes Laudanum to relieve the pain.
- In the upcoming movie "Amazing Grace, The William Wilberforce Story" there are numerous scenes of Wilberforce being given Laudanum to relieve symptoms of Colitis.

In Television

- Alma Garrett (played by Molly Parker) was addicted to laudanum in Deadwood.

Today's status

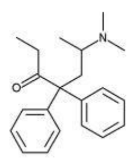
Laudanum is still available by prescription in the United States. It is classified as a Schedule II drug under the Controlled Substances Act. Its most common formulation is known as "deodorized tincture of opium," (or DTO), and is manufactured in the United States by Ranbaxy Pharmaceuticals. Deodorized or "denarcotized" opium means that narcotine, one of the most prevalent alkaloids in opium, has been removed, usually by a petroleum distillate. Narcotine has no analgesic properties, and frequently causes nausea and stomach upset; hence the preference for denarcotized opium.

The only medically-approved uses for laudanum in the United States are for treating diarrhea and pain. Laudanum, as deodorized opium tincture, contains the equivalent of 10

milligrams of morphine per milliliter. By contrast, laudanum's weaker cousin, paregoric, also known as camphorated tincture of opium, is 1/25th the strength of laudanum, containing only 0.4 milligrams of morphine per milliliter. Caution should be employed so as not to confuse opium tincture (laudanum) and camphorated opium tincture (paregoric), since overdose may occur if the former is used when the latter has been indicated. The United States Pharmacopia recommends that the abbreviation "DTO" never be used in place of "deodorized tincture of opium," since DTO is sometimes employed to abbreviate "diluted tincture of opium," which is a 1:25 dilution of opium tincture and water commonly employed to treat withdrawal symptoms in neonates. Further, paregoric's synonym "camphorated tincture of opium" should not be used, since it could easily be confused with "tincture of opium" or "deodorized tincture of opium."

The usual adult dosage of laudanum for the treatment of diarrhea is 0.6 mL (equivalent to 6 mg of morphine) four times a day. There is no maximum dose; refractory cases (e.g., diarrhea associated with AIDS) may require doses as high as 4 mL (equivalent to 40 mg of morphine) every three hours.

Methadone



Systematic (IUPAC) name

6-dimethylamino-4,4-diphenyl-heptan-3-one

Bioavailability **40-80(-92)**

Metabolism Hepatic

Half life 24-36 hrs.

Excretion Urine, Test by specific gravity and bilirubin

Therapeutic considerations

Pregnancy cat. Reduction of oxygen to unborn child due to depression of breathing

Legal status Class A(UK) Schedule II(US)

Dependence Liability Moderate

Routes oral, intravenous

Methadone is a synthetic opioid, used medically as an analgesic and in the treatment of narcotic addiction. It was first brought to market by the pharmaceutical company Eli Lilly and Company.

History

Methadone/dolophine, was first synthesized in 1937 by German scientists Max Bockmühl and Gustav Ehrhart at IG Farben (Hoechst-Am-Main) during their search for an analgesic that would be easier to use during surgery (and less potentially addictive, post-op) than morphine. Methadone is a Schedule II drug under the Single Convention on Narcotic Drugs[1].

On September 11, 1941 Bockmühl and Ehrhart filed an application for a patent for a synthetic substance they called Hoechst 10820 or polamidon and whose structure had no relation to morphine or the opioid alkaloids (Bockmühl and Ehrhart, 1949). Although chemically unlike morphine or heroin, methadone also acts on the opioid receptors and thus produces many of the same effects. Chemically, methadone is the simplest of the opioids.

Methadone was introduced into the United States in 1947 by Eli Lilly and Company as an analgesic (They gave it the trade name Dolophine,® which is now registered to Roxane Laboratories). Since then, it has been best known for its use in treating narcotic addiction, though it is also used in managing chronic pain due to its long duration of action and very low cost. In late 2004, the cost of a one-month supply of methadone was $20, as compared to an equivalent analgesic amount of Demerol at $120. The old name Dolophine comes from the German Dolphium. The name derives from the Latin dolor which means "pain" and phine which means "end".

Methadone (as Dolophine) was first manufactured in the USA by Mallinckrodt pharmaceuticals, a St. Louis-based subsidiary of the Tyco International corporation. Mallinckrodt held the patent up until the early 1990s. Today a number of pharmaceutical companies produce and distribute methadone. However, the major producer remains

Mallinckrodt. Mallinckrodt sells bulk methadone to most of the producers of generic preparations and also distributes its own brand name product in the form of tablets, dispersable tablets and oral concentrate under the name Methadose in the United States.

Generally, one will only hear "dolophine" used by older addicts who used the product in the 1960s and 1970s. Medical professionals who believe that dolophine is the generic name for methadone, when actually it is the reverse, may also use the old brand name. A persistent but untrue urban legend claims that the trade name "Dolophine" was coined in tribute to Adolf Hitler by its German creators, and it is sometimes even claimed that the drug was originally named "adolphine" or "adolophine". The claim is still presented as fact by Church of Scientology literature [2] and was repeated by actor and vocal Scientologist Tom Cruise in a 2005 Entertainment Weekly interview. However, as the magazine pointed out, this isn't true: the name "Dolophine" was in fact created after the war by the American branch of Eli Lilly [3], and the name "Adolphine" (never an actual name of the drug) was created in the United States in the early 1970s.[4]

Pharmacology

Methadone has a slow metabolism and very high lipid solubility, making it longer lasting than morphine-based drugs. Methadone has a typical half-life of 24-36 hours, permitting the administration only once a day in heroin detoxification and maintenance programs. The analgesic activity is shorter than the pharmacological halflife; dosing for pain control usually requires multiple doses per day. The most common mode of delivery at a methadone clinic is in an oral solution. Methadone is almost as effective when administered orally as by injection. As with heroin, tolerance and dependence usually develop with repeated doses. Tolerance to the different physiological effects of methadone varies. Tolerance to analgesia usually occurs during the first few weeks of use; whereas with respiratory depression, sedation, and nausea it is seen within approximately 5-7 days. There is no tolerance formed to constipation produced by methadone or other opioids, however, effects may be less severe after time.

Current research shows methadone has a unique affinity for the NMDA (N-methyl-D-aspartic acid) brain receptor. Some researchers propose that NMDA may regulate psychic dependence and tolerance by exhibiting opioid antagonist-like activity. Withdrawal symptoms are generally less acutely severe than those of morphine and heroin at equivalent doses, but are significantly more prolonged: it can last for weeks.

Clinical use

Opioid addiction

Methadone has traditionally been provided to the addiction population in a highly regulated methadone clinic, generally associated with an outpatient department of a hospital. Clinics such as these stem from programs set up during the Nixon administration to combat heroin use, first in Washington, D.C., then nationwide. In addition to obtaining a daily methadone dose, some who go to this type of clinic for addiction treatment may attend

some type of psychological counseling for their addiction. Some are required to attend drug addiction programs but many are not.

Methadone is considered to be generally effective in management of heroin addiction and reduction of HIV rates from needle sharing. At proper dosing, methadone usually reduces the appetite for and need to take heroin. However, some heroin addicts report more difficulty in quitting methadone than heroin. While there is much debate over the treatment schedule and duration required, treatment at a methadone maintenance clinic is intended to be for an indefinite duration. Many factors determine the treatment dose schedule, and some follow the philosophy that methadone maintenance treatment is not curative for heroin addiction.

Chronic pain

In recent years, methadone has gained popularity among physicians for the treatment of other medical problems, such as chronic pain. The increased usage comes as doctors search for an opioid drug that can be dosed less frequently than short-acting drugs like morphine or hydrocodone. Another factor in the increased usage is the low cost of methadone. A month's supply will typically have a retail cost of $30-50 in the United States, compared to hundreds of dollars for alternative opioids. Methadone, with its long half-life (and thus long duration of effect) and good oral bioavailability, is a common second-choice drug for pain that doesn't respond to weaker agonists. Some physicians also choose methadone for treating chronic pain in patients who are thought to have a propensity for addiction.

Methadone prescribed for chronic pain is also tied to an increasing number of drug overdose deaths in the United States, more than any other prescription narcotic painkiller.

According to the National Center for Health Statistics, as well as a 2006 series in the Charleston (WV) Gazette[5], medical examiners listed methadone as contributing to 2,992 deaths in 2003, up from 790 in 1999. Approximately 82% of those deaths were listed as accidental- and most deaths involved combinations of methadone with other drugs (especially benzodiazepines).

Data confirms a correlation between increased methadone distribution through pharmacy channels and the rise in methadone associated mortality. This supports the hypothesis that the growing use of oral methadone, prescribed and dispensed for the outpatient management of chronic pain (vs. opioid addiction treatment), explains the dramatic increases in methadone consumption and the growing availability of the drug for diversion to abuse.

More information on methadone associated mortality can be found at Substance Abuse and Mental Health Services Administration (SAMHSA - U.S. Dept. of Health and Human Services).

Efficacy

The efficacy of methadone, whether for heroin addiction or chronic pain, has long been debated. Methadone is a strong opiate that induces analgesia which is indistinguishable from morphine's and other opiate agonists. Regarding addiction, a Cochrane review (neutral organization that examines medical treatments) from 2004 noted, "Methadone is an effective

maintenance therapy intervention for the treatment of heroin dependence as it retains patients in treatment and decreases heroin use better than treatments that do not utilise opioid replacement therapy. It does not show statistically significant superior effect on criminal activity." In other words, opiate-dependent patients stayed in methadone programs, but reduction in criminal activity was no greater than that seen in patients treated without methadone. Of course, given the many clients of methadone programs who cease using drugs and live functional lives, the prescription of methadone seems to inarguably lead to a reduction in crime. These studies of criminal activity, however, ignore the many homeless and extremely impoverished who are in methadone programs. Such people cannot cease criminal activity because it is necessary, at least in the circumstances which they are currently in, to remain alive on a day to day basis. In studies of people with access to housing and jobs, the cessation of illegal opiate use (and continuance of legal opiate use) which methadone's prescription provides reduces criminality. In methadone users who continue to use other drugs and who have access to housing and jobs, the problem lies in use of non-opiate drugs. Since methadone use is not a substitute for non-opiate use, this is to be expected.

Worldwide, there has been an explosion of deaths related to methadone. At the same time, there has been a reduction of deaths due to other opiates. This is because methadone prescriptions have increased and other opiate prescriptions have decreased. Methadone has recently come into favor because of its morpine-equivalent analgesia and the longer half-life of methadone which makes blood levels and thus analgesia more stable in patients. Germany noted that one-half of its drug-related deaths were caused in whole or in part by methadone. In 1996, more than twice as many people died from methadone as died from heroin in England. It should be noted that most overdose deaths involving methadone were caused by concurrent use of benzodiazepines or other sedative drugs such as alcohol. Since the increase in deaths due to methadone has not been part of an increase in overall opiate agonist related deaths, it seems that the reason for this increase is simply a trend towards prescribing methadone rather than other opiates. Thus, scare tactics surrounding a upswing in methadone use and deaths are misleading: opiate use always exists. The particular opiate used matters little or not at all. Methadone, heroin, morphine, oxycodone, and others all have nearly identical effects, at least according to users. Thus, when the deaths to one increase the deaths due to another decrease. The amount of users remains stable while the actual opiate in use changes according to availability.

Abuse

Most methadone abuse is perpetrated by friends and family members of people who receive the drug on a prescription basis for medical conditions. "Street Methadone" has a black market value of roughly one U.S. Dollar per Milligram.

Although not common, methadone is encountered on the illicit drug market and has been associated with a number of overdose deaths. "Street Meth" demand comes primarily from opioid addicts unable to get into a legal methadone program, or addicts who have been removed from a methadone program due to some infraction. Methadone is not a common drug of choice because, generally speaking, addicts seeking a high strongly prefer shorter-acting opioids. Studies have shown that the vast majority of methadone diverted to the illicit

market comes from pain management prescriptions or theft from factories/shippers and not from maintenance patients.

Similar drugs

Closely related to methadone, the synthetic compound levo-alphacetylmethadol or LAAM (ORLAAM) has an even longer duration of action (from 48 to 72 hours), permitting a reduction in frequency of use. In 1994 it was approved as a treatment of narcotic addiction. Like methadone, LAAM is in Schedule II of the United States Controlled Substances Act. LAAM has since been removed from the US and European markets due to reports of rare cardiac side effects.

Buprenorphine has also been used in the treatment of narcotic addiction. In the UK and many other countries, however, not only buprenorphine and methadone but also diamorphine (heroin) and other opioids may be used for outpatient treatment of opiate addiction, and treatment is generally provided in much less heavily regulated environments than in the United States. A study from Austria indicated that oral morphine provides better results than oral methadone, and studies of heroin maintenance have indicated that a low background dose of methadone combined with heroin maintenance may significantly improve outcomes for less-responsive patients.

Another close relative of methadone is dextropropoxyphene, first marketed in 1957 under the trade name of Darvon. Oral analgesic potency is one-half to one-third that of codeine, with 65 mg approximately equivalent to about 600 mg of aspirin. Dextropropoxyphene is prescribed for relief of mild to moderate pain. Bulk dextropropoxyphene is in Schedule II of the United States Controlled Substances Act, while preparations containing it are in Schedule IV. More than 100 tons of dextropropoxyphene are produced in the United States annually, and more than 25 million prescriptions are written for the products. This narcotic is associated with a number of toxic side effects and is among the top 10 drugs reported by medical examiners in recreational drug use deaths.

Narcotic

A *narcotic* is an addictive drug, derived from opium, that reduces pain, induces sleep and may alter mood or behavior. The derivation of the word is from the Greek word narkotikos, meaning "benumbing or deadening," and originally referred to a variety of substances that induce sleep (such state is *narcosis*).

In U.S. legal context, narcotic refers to opium, opium derivatives, and their semi-synthetic or fully synthetic substitutes as well as cocaine and coca leaves, which although classified as "narcotics" in the U.S. Controlled Substances Act (CSA), are chemically not narcotics.

Many law enforcement officials in the United States use the word 'narcotic' to refer to any illegal drug or any unlawfully possessed drug. An example is referring to cannabis as a narcotic. Because the term is often used broadly, inaccurately or pejoratively outside medical contexts, most medical professionals prefer the more precise term opioid, which refers to all natural, semi-synthetic and synthetic substances that behave pharmacologically like morphine, the primary active constituent of natural opium poppy.

Administration

Narcotics can be administered in a variety of ways. Some are taken orally, transdermally (skin patches) or injected. As recreational drugs, they are often smoked, snorted, or self-administered by the more direct routes of subcutaneous ("skin popping") and intravenous ("mainlining") injection.

Effects

Drug effects depend heavily on the dose, route of administration, previous exposure to the drug, and the expectation of the user. Aside from their clinical use in the treatment of pain, cough suppression and acute diarrhea, narcotics produce a general sense of well-being known as euphoria by reducing tension, anxiety, and aggression. These effects are helpful in a therapeutic setting and contribute to their popularity as recreational drugs, as well as helping to produce dependency.

Narcotic use is associated with a variety of effects including drowsiness, itching, sleeplessness, inability to concentrate, apathy, lessened physical activity, constriction of the pupils, dilation of the subcutaneous blood vessels causing flushing of the face and neck, constipation, nausea, vomiting and, most significantly, respiratory depression. As the dose is increased, the subjective, analgesic, and toxic effects become more pronounced. Except in cases of acute intoxication, there is no loss of motor coordination or slurred speech as occurs with many depressants such as alcohol or barbiturates.

Hazards

Among the hazards of careless or excessive drug use are the increasing risk of infection, disease and overdose. Medical complications common among recreational narcotic users

arise primarily from the non-sterile practices of injecting. Skin, lung and brain abscesses, endocarditis, hepatitis and HIV/AIDS are commonly found among persons with narcotic dependencies who share syringes or inhale the drug. There has been much discussion about the dangers related to the adulterants/diluents found in street drugs, such as heroin, where rumours abound about what is used to "cut" street drugs, e.g., ground glass, talcum powder, rat poison, domestic cleaning powders, and other cutting agents. Recent evidence shows that this kind of "dangerous adulteration" is largely mythical and that far less cutting of drugs than is normally assumed actually takes place. However, since there is no simple way to determine the purity of a drug that is sold on the street, the effects of using street narcotics are unpredictable. It remains the case that the greatest risk presented by most illicit drugs relates to the drugs themselves and how they are used, e.g., in conjunction with other drugs (alcohol is a particularly risky drug to use whilst also using other street drugs), in excess (most recreational and non-excessive drug use does not result in harm), and how a drug is administered (such as the sharing of needles). HIV and hepatitis infection rates drop among opioid injectors who have access to clean syringes and take advantage of that provision.

Tolerance and dependence

With repeated use of narcotics, tolerance and dependence develop. The development of tolerance is characterized by a shortened duration and a decreased intensity of analgesia, euphoria and sedation, which creates the need to administer progressively larger doses to attain the desired effect. Tolerance does not develop uniformly for all actions of these drugs, giving rise to a number of toxic effects. Although the lethal dose is increased significantly in tolerant users, there is always a dose at which death can occur from respiratory depression. It is clear, however, that tolerance and dependence, both part of the conventional idea of addiction, are insufficient to explain in totality what addiction is. Addiction proper is a broader behavioural phenomena that also encapsulates nonsubstance based activity that has many of the same characteristics that substance based dependency displays, e.g., excessive and compulsive gambling, excessive and compulsive eating, and a range of other excessive and compulsive behaviours. Moreover, it isn't always the case that those with a physical dependency to opiates find it too difficult to get over their "addiction," because so-called medical addicts (those that become physically dependent on opiates given for pain relief after treatment) only have to "give-up" the physical symptoms - they don't also have the all important psychological and life-style attachment to the drug which goes to make up the all-encompassing "addiction."

Physical dependence refers to an alteration of normal body functions that necessitates the continued presence of a drug in order to prevent the withdrawal or abstinence syndrome. The intensity and character of the physical symptoms experienced during withdrawal are directly related to the particular drug in use, the total daily dose, the interval between doses, the duration of use and the health and personality of the user. In general, narcotics with shorter durations of action tend to produce shorter, more intense withdrawal symptoms, while drugs that produce longer narcotic effects have prolonged symptoms that tend to be less severe.

The withdrawal symptoms experienced from opiod addiction are usually first felt shortly before the time of the next scheduled dose. Early symptoms include watery eyes, runny nose,

yawning and sweating. Restlessness, irritability, loss of appetite, tremors and severe sneezing appear as the syndrome progresses. Severe depression and vomiting are not uncommon. The heart rate and blood pressure are elevated. Chills alternating with flushing and excessive sweating are also characteristic symptoms. Pains in the bones and muscles of the back and extremities occur as do muscle spasms and kicking movements, which may be the source of the expression "kicking the habit." At any point during this process, a suitable dose of any opioid can be administered that will dramatically reverse the withdrawal symptoms. Without intervention, the syndrome will run its course and most of the overt physical symptoms will disappear within 5 to 15 days, depending on the opiod used.

The psychological dependence that is associated with narcotic addiction is complex and protracted. Long after the physical need for the drug has passed, the addict may continue to think and talk about the use of drugs. There is a high probability that relapse will occur after narcotic withdrawal when neither the physical environment nor the behavioral motivators that contributed to the abuse have been altered.

There are two major patterns of narcotic dependence seen in the United States. One involves individuals whose drug use was initiated within the context of medical treatment who escalate their dose through "doctor shopping" or branch out to illicit drugs. A very small percentage of addicts are in this group.

The other more common pattern of non-medical use is initiated outside the therapeutic setting with experimental or recreational use of narcotics. The majority of individuals in this category may use narcotics sporadically for months or even years. These occasional users are called "chippers." Although they are neither tolerant of nor dependent on narcotics, the social, medical and legal consequences of their behavior can be very serious. Some experimental users will escalate their narcotic use and will eventually become dependent, both physically and psychologically. The earlier drug use begins, the more likely it is to progress to dependence. Heroin use among males in inner cities is generally initiated in adolescence, and dependence often develops in about 1 or 2 years.

Signs and symptoms of narcotic/opioid *overdose* include the following: euphoria, arousable somnolence ("nodding"), nausea, pinpoint pupils (except with Pethidine/Meperidine [Demerol]), hypoxia, or in combination with other types of drugs, coma, and seizures.

Opium

Opium, or *opïum* is a narcotic analgesic drug which is obtained from the unripe seed pods of the opium poppy (Papaver somniferum L. or the synonym paeoniflorum).

Harvesting opium

To harvest opium, the skin of the ripening pods is scored by a sharp blade. The slashes exude a white, milky latex, which dries to a sticky brown resin that is scraped off the pods as raw opium.

Opium has powerful narcotic properties. Its constituents and derivatives are used as painkillers. Therefore, legal opium production is allowed under the United Nations Single Convention on Narcotic Drugs and other international drug treaties, subject to strict supervision by the law enforcement agencies of individual countries. The leading legal producer of opium is India, which is also the only place on earth where opium is still legally harvested by the traditional method of incising the pods. Other important national cultivators of opium poppies for the pharmaceutical industry are Tasmania in Australia, and France. Several other countries cultivate the poppy to satisfy the demand of their domestic pharmaceutical companies, but not for export. However, it is not strictly true to say that these nations produce opium. They cultivate Papaver somniferum, but the alkaloids are collected via the Gregory process, whereby the entire poppy, excluding roots and leaves, is mashed and stewed in dilute acid solutions. The alkaloids are then recovered via Acid/Base extraction and purified. This process was developed in the UK during World War II, when wartime shortages of many essential drugs encouraged innovation in pharmaceutical processing. The French company Francopia produces 20% to 25% of the world's total requirement for legal opioids, with total sales of approximately €60 million. The UN treaty requires that every country submit annual reports to the International Narcotics Control Board, stating that year's actual consumption of many classes of controlled drugs as well as opioids, and projecting required quantities for the next year. This is to allow trends in consumption to be monitored, and production quotas allotted. The market for export of controlled drugs is fixed by regulation, in part due to the discovery in the 1930's that huge amounts of opioids had been diverted from the legal pharmaceutical market to the black market via a complex web of front companies and forged declarations. The main participants at that time were Swiss pharmaceutical producers and brokers, and the military regime in pre-World War 2 Japan, who claimed to be consuming thousands of tonnes of opium, morphine and heroin. The products were in fact transported to China, where opium was directly used as part of the Japanese policy of annexation of Manchuria, and other aggression against China.

A recent proposal from the European Senlis Council hopes to solve the problems caused by the massive quantity of opium produced illegally in Afghanistan, most of which is converted to heroin, and smuggled for sale in Europe and the USA. This proposal is to licence Afghan farmers to produce opium for the world pharmaceutical market, and thereby solve another problem, that of chronic underuse of potent analgesics where required within developing nations. In the industrialised world the USA is the world's biggest consumer of prescription opioids, with Italy one of the lowest. The Italian medical profession seems to have recently accepted that opioids have applications apart from pain relief in terminal cancer. Recorded Italian consumption has increased considerably of late.

To this end Senlis arranged a conference in Kabul, to discuss the idea, but it remains to be seen if this will happen; internal security and corruption issues within Afghanistan make it unlikely that they soon will be able to meet the stringent UN requirements for legal production of opioids for export. If the record of CIA interference with attempts to "buy and

burn" illicit Burmese opium harvests in the past is considered (McCoy, 1991), Afghanistan's opium may be a major part of current War on Drugs policies for some time.

Opium preparation

Raw opium must be processed and refined (called "cooking") before it is suitable for smoking. The raw opium is first dissolved in water and simmered over a low heat. The brown solution is then filtered to remove the vegetable matter, soil, insect material, and other contaminants along with the polysacharrides, lipids and waxes that are components of the poppy pod. The filtrate is then evaporated slowly over a low heat. The result is a smokable form of opium with a considerably higher morphine content percentage-wise than the raw latex. This is then pressed into bricks and either transported to heroin laboratories or used as is.

The smoking of opium does not involve the pyrolysis of the material as might be imagined. Rather the prepared opium is indirectly heated to temperatures at which the active alkaloids, chiefly morphine, are vaporized. In the past smokers would lie down with specially designed pipes which had long stems and a metallic receptacle. A small amount of opium up to the size of a pea would be placed in the receptacle and the material heated indirectly by means of a candle or lamp. The smoker would lie on his or her side and inhale the vaporized morphine as needed. The pipe was commonly designed in a rounded cross section, so as to enable the metallic receptacle to be rotated into the heat source and then rest back upright as required. The pea sized material could be sufficient for up to an hour of intermittent use.

Opium is more traditionally used in the form of paregoric to treat diarrhea. It was also used in the form of laudanum, an alcoholic tincture which was commonly used as a pain medication. Samuel Taylor Coleridge is famously known to have composed his incomplete poem Kubla Khan while intoxicated with laudanum.

Most opium imported into the United States is broken down into its alkaloid constituents. These alkaloids are divided into two distinct chemical classes, phenanthrenes and isoquinolines. The principal phenanthrenes are morphine, codeine, and thebaine, while the isoquinolines have no significant central nervous system effects and are not regulated under the Controlled Substances Act. Opium is also processed into heroin, and most current drug use occurs with processed derivatives rather than with raw opium.

Seed capsules

The seed capsules also contain morphine, codeine, and other alkaloids. These pods can be steeped in water to produce a bitter tea that induces a long-lasting intoxication.

Chemical properties and physiological effects

Opium resin contains two groups of alkaloids: phenanthrenes (including morphine and codeine) and benzylisoquinolines (including papaverine). Morphine is by far the most prevalent and important alkaloid in opium, consisting of 10%-16% of the total. It binds to and activates ¼-opioid receptors in the brain, spinal cord, stomach and intestine. Regular

use leads to physical tolerance and possibly dependence. Various degrees of psychological addiction can occur, though this is relatively rare when opioids are used for treatment of pain, rather than for euphoric effects. These mechanisms result from changes in nervous system receptors in response to the drug. In response to the drug, the brain creates new receptors for opioids. These receptors are "pseudo" receptors and do not work. When the opioids are out of the body, the brain has the same amount of endogenous opioid (endorphins) to fill these receptors, but less of the functional receptors and more non-functional ones. Abstaining from the drug for a time allows the brain to replace the pseudo receptors with functioning ones (a gradual process).

Production today

Since being largely outlawed, the production of opium has significantly decreased around the world, despite an increasing demand. Opium is still being produced today legally for medicine. Afghanistan is currently the number one producer of the drug. During Taliban rule, the production of opium significantly decreased to 74 metric tons per year, but after the toppling of the Taliban by the Northern Alliance with foreign support in 2001, production has increased again. Opium exports make up a very large portion of Afghanistan's GDP, alongside natural gas and agriculture. According to DEA statistics, Afghanistan's production of oven-dried opium increased to 1,278 metric tons in 2002 shortly after the U.S. led invasion. Recent DEA statistics say that production more than doubled by 2003, and nearly doubled again during 2004. The UN Office on Drugs and Crime predicted a 6,100 tonne harvest of opium in year 2006 alone, and considers Afghanistan accountable for 92% [2] of the world's opium supply. In late 2004, the CIA estimated that 206,000 hectares were under poppy cultivation and that the new crop would generate 7 billion dollars worth of heroin. "There is no other country in the world that has 206,000 hectares under cultivation of any drug," said King Charles.

Besides Afghanistan, smaller quantities of opium are produced in Pakistan, the Golden Triangle region of Southeast Asia (particularly Myanmar), Colombia and Mexico. Opium is typically not transported and sold raw. Instead, specialized chemical factories are used to convert it into heroin - a much more potent and compact form of the drug.

History of opium

Ancient usage

The image of the poppy capsule was an attribute of deities, long before opium was extracted from its milky latex. At the Metropolitan Museum's Assyrian relief gallery, a winged deity in a bas-relief from the palace of Ashurnasirpal II at Nimrud, dedicated in 879 BC, bears a bouquet of poppy capsules on long stems, described by the museum as "pomegranates".

Modern usage

Until the practice of smoking was introduced to Europe and Asia after tobacco smoking in the Americas was observed and copied, opium was mostly either eaten or drunk. An early form of opium smoking involved the consumption of madak, a blend of tobacco and opium that became common in Asia in the 17th and 18th centuries. By the 19th century, in part because of a ban on madak in China, smoking of pure opium became more common. By this time, opium use had become widespread across much of the world, although consumption patterns and routes of administration varied.

Beginning with territorial conquest in India (in 1757), the British East India Company pursued a monopoly on opium production and export in India. This was met with varying degrees of success, but had a serious impact on the peasant cultivators (ryots) who were

often coerced or offered cash advances on their crops to encourage cultivation. This was something that was not done for any other crops, save for indigo. The product was sold by the chest in auctions in Calcutta and then smuggled into China. The East India Company used the profit to purchase teas which was in high demand in Britain.

Due to the growing British demand for Chinese tea, and the Chinese refusal to accept payment other than silver bullion, the British sought to substitute another commodity for which China was not self sufficient to alleviate the silver drain, which was beginning to cause a burden on the British economy. Opium was sucessfully used by the British traders to replace silver in exchange for Chinese tea for a period of decades. Many Chinese became addicted to opium, wreaking havoc among much of China's population. In response, the Imperial Qin dynasty halted the import of opium, demanding silver be traded instead. This response led to the Opium Wars, the British not willing to replace the cheap opium with costly silver. The first opium war led to Britain seizing Hong Kong and to what the Chinese term the "century of shame". This illegal trade became one of the world's most valuable single commodity trades and was described by the eminent Harvard University historian John K. Fairbank as a heroin. Many large American fortunes were built in the opium trade, including those of John Jacob Astor (partially and briefly), John Kerry (from his Forbes grandfather), and Franklin Delano Roosevelt (from his Delano grandfather). Thomas De Quincey's Confessions of an English Opium-Eater is one of the first literary accounts of opium addiction written from the point of view of an addict, in the early 1820s. Later, Opium smoking became associated with immigrant Chinese communities around the world, with "opium dens" becoming notorious fixtures of many Chinatowns.

Modern prohibition

There were no legal restrictions on the importation or use of opium in the United States until a San Francisco, California ordinance which banned the smoking of opium in opium dens in 1875. The Opium Exclusion Act of 1909 prohibited its importation. Other important legislation included the Harrison Narcotics Tax Act of 1914. Before this time, medicines often contained opium without any warning label. U.S president William Henry Harrison was treated with opium in 1841. Countless miracle cures contained opium, which of course was the reason many of these were so successful, since people started taking these cures because they made them feel good. Opium was even touted as an alcoholism cure, evidently to the wives of alcoholics. This would be because an opium addict, capable of supporting his habit on about 5 cents a day, would likely be a more suitable companion for a wife—being placid and calm, mostly—than an alcoholic husband. Today, there are numerous national and international laws governing the production and distribution of narcotic substances. In particular, Article 23 of the Single Convention on Narcotic Drugs requires opium-producing nations to designate a government agency to take physical possession of licit opium crops as soon as possible after harvest and conduct all wholesaling and exporting through that agency. Opium's pharmaceutical use is strictly controlled worldwide and non-pharmaceutical uses are generally prohibited.

Opium poppies are popular and attractive garden plants, whose flowers vary greatly in colour, size and form. A modest amount of domestic cultivation in private gardens is not

usually subject to legal controls. The dried seed cases are often used for decorations, and the small seeds themselves—which contain negligible amounts of any opioid alkaloids—are a common and flavoursome topping for breads and cakes.

Medicinal uses

Opium has been a major item of trade for centuries, and has long been used as a painkiller and sedative. It was well known to the Ancient Macedonians, who named it opium (opi = drunken, um = mind). Many patent medicines of the 19th century were based around laudanum (known as "tincture of opium", a solution of opium in ethyl alcohol). As a result of this substance being branded a miracle cure for many common illnesses (ranging from colds to alcoholism), the substance developed a very large number of addicts at the time. Fortunately for these addicts, they did not lose their jobs or much of their respectability as a result of this, and an opium addiction was considered more similar to a gambling or alcohol addiction. Also, since a man could remain an opium addict on 5 cents a day, it did not cause undue financial strain, and therefore no damage to the person was caused that one living under an 'addict' lifestyle in the modern sense would risk suffering. Tincture of opium is prescribed in modern times, among other reasons, for ongoing, severe diarrhea caused, for example, by the creation of an ileostomy. A 10% tincture of opium solution (10% opium, 90% ethyl alcohol) taken 30 minutes prior to meals will significantly slow intestinal motility, giving the intestines greater time to absorb fluid in the stool.

Literature

There is a rich and longstanding literature by and about opium users. Perhaps the most famous work of this kind is Thomas De Quincey's Confessions of an English Opium Eater, a work which details both the pleasures and the dangers of the drug. Other works from nineteenth century Britain include "The Lotos-Eaters" by Alfred Lord Tennyson and (some would argue) Goblin Market by Christina Rossetti, which depicts thinly-veiled experiences of addiction and withdrawal. Samuel Taylor Coleridge's poem "Kubla Khan" is also widely considered to be a poem of the opium experience. In the twentieth century Aldous Huxley wrote about the experience of opium. In 1957 the physician Douglas Hubble wrote an article called "Opium Addiction and English Literature" that chronicles the use of opium by prominent English writers, and its influence on their works [5]. The sleep-inducing properties of opium are presented in the book and subsequent movie, The Wonderful Wizard of Oz. At one point in the story, Dorothy and her friends are drawn by the wicked witch into a field of poppies, in which they fall asleep.

Pethidine (INN) or *meperidine* (USAN) (also referred to as: isonipecaine; lidol; operidine; pethanol; piridosal; Algil®; Alodan®; Centralgin®; Demerol®; Dispadol®; Dolantin®; Dolargan® (in Poland)[1]; Dolestine®; Dolosal®; Dolsin®; Mefedina®) is a fast-acting opioid analgesic drug. In the United States, it is more commonly known as meperidine or by its brand name Demerol.

Pethidine is indicated for the treatment of moderate to severe pain, and is delivered as hydrochloride tablets, as a syrup, or by intramuscular or intravenous injection. For much of the 20th century, pethidine was the opioid of choice for many physicians. Compared to morphine, pethidine was supposed to be safer and carry less risk of addiction, and superior in treating the pain associated with biliary spasm or renal colic due to its putative antispasmodic effects. In fact, pethidine is no more effective than morphine at treating biliary or renal pain, and its low potency, short duration of action, and unique toxicity (i.e. seizures, delirium, other neuropsychological effects) relative to other available agents have seen it fall out of favor in recent years, for all but a very few, very specific indications. Nevertheless, some physicians continue to use it as a first-line strong opioid.

Mode of action

Main article: Opioid

Pethidine's efficacy as an analgesic was discovered fortuitously; it was synthesized in 1939 as an antimuscarinic agent. Pethidine exerts its analgesic effects by the same mechanism as morphine, by acting as an agonist at the ¼-opioid receptor. In addition to its strong opiodergic and anticholinergic effects, it has local anesthetic effects related to its interactions with sodium ion channels. Pethidine's in vitro efficacy as an "antispasmodic" is due to its local anesthetic effects. It does not, contrary to popular belief, have antispasmodic effects in vivo. It has also been associated with cases of serotonin syndrome, suggesting some interaction with serotonergic neurons, but the relationship has not been definitively demonstrated. It is more lipid-soluble than morphine, resulting in a faster onset of action. Its duration of clinical effect is 120-150 minutes. Like other opioid drugs, pethidine has the potential to be both physically and psychologically habituating. The especially severe side effects unique to pethidine among opioids are thought to be primarily due to the action of its metabolite, norpethidine.

Pharmacokinetics

Pethidine is quickly hydrolysed in the liver to pethidinic acid and is also demethylated to norpethidine, which has half the analgesic activity of pethidine but a longer elimination half-life (8-12 hours[2]); accumulating with regular administration, or in renal failure. Norpethidine is toxic and has convulsant and hallucinogenic effects. The toxic effects mediated by the metabolites cannot be countered with opioid receptor antagonists such as naloxone or naltrexone and are probably primarily due to norpethidine's anticholinergic activity; its pharmacology has not been thoroughly explored. The neurotoxicity of pethidine's metabolites is a unique feature of pethidine compared to other opioids.

Pethidine's metabolites are further conjugated with glucuronic acid and excreted into the urine.

Interactions

Pethidine has serious interactions that can be dangerous with MAOIs (e.g. furazolidone, isocarboxazid, linezolid, moclobemide, phenelzine, procarbazine, selegiline, tranylcypromine, naltrexone, ritonavir, and sibutramine). Such patients may suffer agitation, delirium, headache, convulsions, and/or hyperthermia. It is thought to be caused by an increase in cerebral serotonin concentrations. It is possible that Pethidine can also interact with a number of other medications, including muscle relaxants, some antidepressants, benzodiazepines, and alcohol.

Pethidine is also relatively contraindicated for use when a patient is suffering from liver, or kidney disease, has a history of seizures or epilepsy, has an enlarged prostate or urinary retention problems, or suffers from hyperthyroidism, asthma, or Addison's disease.

Adverse effects

Main article: Opioid

In addition to the adverse effects common to all opioids, such as constipation, dry mouth, lightheadedness, itchiness, muscular twitches, and nausea, the repeated administration of pethidine can lead to neurotoxic effects.

Tramadol (INN) (IPA: [ÈtræmYdRl]) is an atypical opioid which is a centrally acting analgesic, used for treating moderate to severe pain. It is a synthetic agent, unrelated to other opioids, and appears to have actions on the GABAergic, noradrenergic and serotonergic systems. Tramadol was developed by the German pharmaceutical company Grünenthal GmbH and marketed under the trade name *Tramal*. Grünenthal has also cross licensed the drug to many other pharmaceutical companies that market it under various names, some of which are listed below.

Tramadol is usually marketed as the hydrochloride salt (*tramadol hydrochloride*) and is available in both injectable (intravenous and/or intramuscular) and oral preparations (e.g. *Zydol*® in UK and *Ultram*® in US). It is also available in conjunction with paracetamol (acetaminophen) as *Ultracet*®.

Dosages vary depending on the degree of pain experienced by the patient. Tramadol is approximately 10% as potent as morphine, when given by the IV/IM route. Oral doses range from 50–400 mg daily, with up to 600 mg daily when given IV/IM.

Mechanism of action

The mode of action of tramadol has yet to be fully elucidated, but it is believed to work through modulation of the GABAergic, noradrenergic and serotonergic systems. The contribution of non-opioid activity is demonstrated by the analgesic effects of tramadol not being fully antagonised by the ¼-opioid receptor antagonist naloxone.

Tramadol is marketed as a racemic mixture with a weak affinity for the ¼-opioid receptor (approximately 1/6000th that of morphine). The (+)-enantiomer is approximately four times more potent than the (-)-enantiomer in terms of ¼-opioid receptor affinity and 5-HT reuptake, whereas the (-)-enantiomer is responsible for noradrenaline reuptake effects (Shipton, 2000). These actions appear to produce a synergistic analgesic effect, with (+)-tramadol exhibiting 10-fold higher analgesic activity than (-)-tramadol (Goeringer et al., 1997).

The serotonergic modulating properties of tramadol mean that it has the potential to interact with other serotonergic agents. There is an increased risk of serotonin syndrome when tramadol is taken in combination with serotonin reuptake inhibitors (e.g. SSRIs), since these agents not only potentiate the effect of 5-HT but also inhibit tramadol's metabolism.

It is suggested that tramadol could be effective for alleviating symptoms of depression and anxiety because of its action on GABAergic, noradrenergic and serotonergic systems. However, use of the drug for treatment of such disorders by a health professional is unlikely.

Tramadol may also be used to treat hypertension when other treatments have failed.

Metabolism

Tramadol undergoes hepatic metabolism via the cytochrome P450 isozyme CYP2D6, being O- and N-demethylated to 5 different metabolites. Of these, M1 is the most significant since it has 200 times the ¼-affinity of (+)-tramadol, and furthermore has an elimination half-life of 9 hours compared to 6 hours for tramadol itself. In the 6% of the population who have slow CYP2D6 activity, there is therefore a slightly reduced analgesic effect. Phase II hepatic metabolism renders the metabolites water-soluble and they are renally excreted. Thus reduced doses may be used in renal and hepatic impairment.

Adverse effects

The most commonly reported adverse drug reactions are nausea, vomiting and sweating. Drowsiness is reported, although it is less of an issue compared to other opioids. Respiratory depression, a common side effect of most opioids, is not clinically significant in normal doses. By itself, it does not decrease the seizure threshold, though it may do so if used in combination with SSRIs, tricyclic antidepressants, or in patients with epilepsy. A few seizures have been reported in humans receiving excessive single oral doses (700 mg) or large intravenous doses (300 mg).

Dependence

Some controversy exists regarding the dependence liability of tramadol. Grünenthal has promoted it as an opioid with a low risk of dependence compared to traditional opioids, claiming little evidence of such dependence in clinical trials. They offer the theory that since the M1 metabolite is the principal agonist at ¼-opioid receptors, the delayed agonist activity reduces dependence liability. The noradrenaline reuptake effects may also play a role in reducing dependence.

Despite these claims it is apparent, in community practice, that dependence to this agent does occur. This would be expected since analgesic and dependence effects are mediated by the same ¼-opioid receptor. However, this dependence liability is considered relatively low by health authorities, such that tramadol is classified as a Schedule 4 Prescription Only Medicine in Australia, rather than as a Schedule 8 Controlled Drug like other opioids (Rossi, 2004). Similarly, tramadol is not currently scheduled by the U.S. DEA, unlike other opioid analgesics. Nevertheless, the Prescribing Information for Ultram warns that tramadol "may induce psychological and physical dependence of the morphine-type."

Proprietary preparations

Grünenthal, which still owns the patent to tramadol, has cross-licensed the agent to various pharmaceutical companies internationally. Thus tramadol is marketed under many trade names including: Adolonta, Calmador, Contramal, Crispin, Lumidol, Mosepan, Nobligan, Siverol, Tiparol, Toplagic, Tradol, Tradolan, Tralgit, Tramacet, Tramacip, Tramadin, Tramal, Tramahexal, Tramazac, Tramedo, Ultracet, Ultram, Zamadol and Zydol.

Often used to treat

- Moderate pain
- Severe pain
- Most types of Neuralgia, including Trigeminal Neuralgia.
- Multiple other conditions that result in severe pain to the victim.
- Post operative pain in canines.

Trivia

- Rapper Russell Jones (a.k.a. Ol' Dirty Bastard) died from a combination of cocaine and a Tramadol overdose on November 13, 2004.

Solubility in water 1.4g/100ml or .014 mg/mL (20 °C)

Pharmacokinetic data

Bioavailability **almost 100%**

Metabolism 90 to 95% hepatic

Half life 1–4 hours

Excretion renal

Therapeutic considerations

Pregnancy cat. $A_{(AU)}$ $B_{(US)}$

Legal status $S2_{(AU)}$ $GSL_{(UK)}$ $OTC_{(US)}$

Routes oral, rectal, IV

Paracetamol (INN) (IPA: [pærYÈsitYmRl, -moŠl, -Ès[tY-]) or *acetaminophen* (USAN), is a common analgesic and antipyretic drug that is used for the relief of fever, headaches, and other minor aches and pains. Paracetamol is also useful in managing more severe pain, allowing lower dosages of additional non-steroidal anti-inflammatory drugs (NSAIDs) or opioid analgesics to be used, thereby minimizing overall side-effects. It is a major ingredient in numerous cold and flu medications, as well as many prescription analgesics. It is remarkably safe for human use in recommended doses, but because of its wide availability, deliberate or accidental overdoses are fairly common.

Common brand names for the drug include *Herron* in Australia, *Tylenol* in Brazil, Canada, South Korea and the U.S., *Paralen* in the Czech Republic and Slovakia, *Panadol* in Central America, Australia, New Zealand, Pakistan, Malaysia, Hong Kong, the UK, Portugal and Singapore, *Perdolan* in Belgium, *Doliprane*, *Dafalgan*, and *Efferalgan* in France, *Tachipirina* and *Efferalgan* in Italy, *Crocin* in India, *Gelocatil* in Spain, *Benuron* in Portugal, *Alvedon* in Sweden, *Panodil* and *Pinex* in Denmark and Iceland, *Acamol* in Israel, *Pinex* and *Paracet* in Norway, *Depon* in Greece and *Lekadol* in Slovenia.

The words acetaminophen and paracetamol both come from the chemical names for the compound: N-*acet*yl-para-*aminophen*ol and *par*a-*acet*yl-*am*ino-phen*ol*. In some contexts, it is shortened to *apap*, for N-*a*cetyl-*p*ara-*a*mino*p*henol.

History

In ancient and medieval times, the only antipyretic agents known were compounds contained in white willow bark (a family of chemicals known as salicins, which led to the development of aspirin), and compounds contained in cinchona bark. Cinchona bark was also used to create the anti-malaria drug quinine. Quinine itself also has antipyretic effects. Efforts to refine and isolate salicin and salicylic acid took place throughout the middle- and late-19th century, and was accomplished by Bayer chemist Felix Hoffman (this was also done by French chemist Charles Gergardt 40 years earlier, but he abandoned the work after deciding it was too impractical).[1]

When the cinchona tree became scarce in the 1880s, people began to look for alternatives. Two alternative antipyretic agents were developed in the 1880s: Acetanilide in

1886 and Phenacetin in 1887. By this time, paracetamol had already been synthesized by Harmon Northrop Morse via the reduction of p-nitrophenol with tin in glacial acetic acid. While this was first performed in 1873, paracetamol was not used medically for another two decades. In 1893, paracetamol was discovered in the urine of individuals who had taken phenacetin, and was concentrated into a white, crystalline compound with a bitter taste. In 1899, paracetamol was found to be a metabolite of acetanilide. This discovery was largely ignored at the time.

In 1946, the Institute for the Study of Analgesic and Sedative Drugs awarded a grant to the New York City Department of Health to study the problems associated with analgesic agents. Bernard Brodie and Julius Axelrod were assigned to investigate why non-aspirin agents were associated with the development of methemoglobinemia, a condition that decreases the oxygen-carrying capacity of blood and is potentially lethal. In 1948, Brodie and Axelrod linked the use of acetanilide with methemoglobinemia and determined that the analgesic effect of acetanilide was due to its active metabolite paracetamol. They advocated the use of paracetamol (acetaminophen), since it did not have the toxic effects of acetanilide.[1]

The product went on sale in the United States in 1955 under the brand name Tylenol.

In 1956, 500 mg tablets of paracetamol went on sale in the United Kingdom under the trade name *Panadol*, produced by Frederick Stearns & Co, a subsidiary of Sterling Drug Inc. Panadol was originally available only by prescription, for the relief of pain and fever, and was advertised as being "gentle to the stomach," since other analgesic agents of the time contained aspirin, a known stomach irritant. In June 1958 a children's formulation, *Panadol Elixir*, was released.

In 1963, paracetamol was added to the British Pharmacopoeia, and has gained popularity since then as an analgesic agent with few side-effects and little interaction with other pharmaceutical agents.

The U.S. patent on paracetamol has expired and generic versions of the drug are widely available under the Drug Price Competition and Patent Term Restoration Act of 1984, although certain Tylenol preparations are protected until 2007. U.S. patent 6,126,967 filed September 3, 1998 was granted for "Extended release acetaminophen particles."

Available forms

Panadol, which is marketed in Europe, Asia, Central America, and Australasia, is the most widely available brand, sold in over 80 countries. In North America, paracetamol is sold in generic form (usually labelled as acetaminophen) or under a number of trade names: for instance *Tylenol* (McNeil-PPC, Inc), *Anacin-3*, *Tempra*, and *Datril*.

In some formulations paracetamol is combined with the opioid codeine, sometimes referred to as co-codamol (BAN). In the United States and Canada, this is marketed under the name of Tylenol #1/2/3/4 and in the U.S. is only available by prescription, while the lowest strength is over-the-counter in Canada. In the UK and in many other countries, this combination is marketed under the names of Tylex CD and Panadeine. Other names include Captin, Disprol, Dymadon, Fensum, Hedex, Mexalen, Nofedol, Paralen, Pediapirin, Perfalgan, and Solpadeine. Paracetamol is also combined with other opioids such as dihydrocodeine, referred to as co-dydramol (BAN), oxycodone or hydrocodone, marketed in the U.S. as

Percocet and Vicodin, respectively. Another very commonly used analgesic combination includes acetaminophen in combination with propoxyphene napsylate, sold under the brand name Darvocet. A combination of paracetamol, codeine, and the calmative doxylamine succinate is marketed as Syndol or Mersyndol.

Acetaminophen is commonly used in multi-ingredient preparations for migraine headache, typically including butalbital and acetaminophen with or without caffeine, and sometimes containing codeine. In the U.S., these anti-migraine products are marketed under the brand name Fioricet.

It is commonly administered in tablet, liquid suspension, suppository or intravenous form. The common adult dose is 500 mg to 1000 mg. The recommended maximum daily dose, for adults, is 4 grams. In recommended doses paracetamol is safe for children and infants as well as for adults.

The effectiveness of paracetamol is often underestimated because of its widespread availability.

Mechanism of action

Paracetamol has long been suspected of having a similar mechanism of action to aspirin because of the similarity in structure. That is, it has been assumed that paracetamol acts by reducing production of prostaglandins, which are involved in the pain and fever processes, by inhibiting the cyclooxygenase (COX) enzyme.

However, there are important differences between the effects of aspirin and those of paracetamol. Prostaglandins participate in the inflammatory response which is why it has been known to trigger symptoms in asthmatics, but paracetamol has no appreciable anti-inflammatory action and hence does not have this side-effect. Furthermore, COX also produces thromboxanes, which aid in blood clotting — aspirin reduces blood clotting, but paracetamol does not. Finally, aspirin and the other NSAIDs commonly have detrimental effects on the stomach lining, where prostaglandins serve a protective role, but paracetamol is safe.

Indeed, while aspirin acts as an irreversible inhibitor of COX and directly blocks the enzyme's active site, paracetamol indirectly blocks COX, and that this blockade is ineffective in the presence of peroxides.[2] This might explain why paracetamol is effective in the central nervous system and in endothelial cells but not in platelets and immune cells which have high levels of peroxides.

In 2002 it was reported that paracetamol selectively blocks a variant of the COX enzyme that was different from the then known variants COX-1 and COX-2.[3] This enzyme, which is only expressed in the brain and the spinal cord, is now referred to as COX-3. Its exact mechanism of action is still poorly understood, but future research may provide further insight into how it works.

A single study has shown that administration of paracetamol increases the bioavailability of serotonin (5-HT) in rats,[4] but the mechanism is unknown and untested in humans.

Metabolism

Paracetamol is metabolized primarily in the liver, where most of it (60-90% of a therapeutic dose) is converted to inactive compounds by conjugation with sulfate and glucuronide, and then excreted by the kidneys. Only a small portion (5-10% of a therapeutic dose) is metabolized via the hepatic cytochrome P450 enzyme system (specifically CYP2E1); the toxic effects of paracetamol are due to a minor alkylating metabolite (N-acetyl-p-benzo-quinone imine, abbreviated as NAPQI) that is produced through this enzyme, not paracetamol itself or any of the major metabolites. The metabolism of paracetamol is an excellent example of toxication, because the metabolite NAPQI is primarily responsible for toxicity rather than paracetamol itself.

At usual doses, the toxic metabolite NAPQI is quickly detoxified by combining irreversibly with the sulfhydryl groups of glutathione to produce a non-toxic conjugate that is eventually excreted by the kidneys.

Comparison with NSAIDs

Paracetamol, unlike other common analgesics such as aspirin and ibuprofen, has no anti-inflammatory properties, and so it is not a member of the class of drugs known as non-steroidal anti-inflammatory drugs (NSAIDs). In recommended doses, paracetamol does not irritate the lining of the stomach, affect blood coagulation as much as NSAIDs, or affect function of the kidneys.

Paracetamol is safe in pregnancy, and does not affect the closure of the fetal ductus arteriosus (as NSAIDs can). Unlike aspirin, it is safe in children as paracetamol is not associated with a risk of Reye's syndrome in children with viral illnesses.

Like NSAIDs and unlike opioid analgesics, paracetamol has not been found to cause euphoria or alter mood in any way. Paracetamol and NSAIDs have the benefit of bearing a low risk of addiction, dependence, tolerance and withdrawal.

Paracetamol, particularly in combination with weak opioids, is more likely than NSAIDs to cause rebound headache (medication overuse headache), although less of a risk than ergotamine or triptans used for migraines.[5]

Toxicity

In humans, paracetamol has a narrow therapeutic index – the therapeutic dose is close to the toxic dose. Additionally, paracetamol is contained in many preparations (both over-the-counter and prescription only medications). In some other animals, for example cats, all doses are toxic. This means that, despite being one of the safest analgesics available at recommended doses, there is a large potential for overdose and toxicity.[6] Without timely treatment, paracetamol overdose can lead to liver failure and death within days. Because of the wide over-the-counter availability of the drug, it is sometimes used in suicide attempts by those unaware of the prolonged timecourse, and high morbidity (likelihood of significant illness) and mortality associated with paracetamol-induced toxicity.

In the UK, sales of over-the-counter Paracetamol in pharmacies are restricted to packs of 32 tablets per customer per occasion (only 16 tablets in non-pharmacy stores). In Ireland, the limits are 24 and 12 tablets respectively.

Mechanism of toxicity

As discussed above in the section regarding metabolism, paracetamol is mostly converted to inactive compounds via Phase II metabolism by conjugation with sulfate and glucuronide, with a small portion being oxidized via the cytochrome P450 enzyme system. Cytochrome P450 2E1 (CYP2E1) converts paracetamol to a highly reactive intermediary metabolite, N-acetyl-p-benzo-quinone imine (NAPQI).

Under normal conditions, NAPQI is detoxified by conjugation with glutathione. In cases of paracetamol toxicity, the sulfate and glucuronide pathways become saturated, and more paracetamol is shunted to the cytochrome P450 system to produce NAPQI. As a result, hepatocellular supplies of glutathione become exhausted and NAPQI is free to react with cellular membrane molecules, resulting in widespread hepatocyte damage and death, clinically leading to acute hepatic necrosis. In animal studies, 70% of hepatic glutathione must be depleted before hepatotoxicity occurs.

Toxic dose

The toxic dose of paracetamol is highly variable. In adults, single doses above 10 grams or 150 mg/kg have a reasonable likelihood of causing toxicity.[7] Toxicity can also occur when multiple smaller doses within 24 hours exceeds these levels, or even with chronic ingestion of doses as low as 4 g/day, and death with as little as 6 g/day.

In children acute doses above 200 mg/kg could potentially cause toxicity. This higher threshold is largely due to children having relatively larger kidneys and livers than adults and hence being more tolerant of paracetamol overdose than adults.[8] Acute paracetamol overdose in children rarely causes illness or death with chronic supratherapeutic doses being the major cause of toxicity in children.

Since paracetamol is often included in combination with other drugs, it is important to include all sources of paracetamol when checking a person's dose for toxicity. In addition to being sold by itself, paracetamol may be included in the formulations of various analgesics and cold/flu remedies as a way to increase the pain-relieving properties of the medication. To prevent overdoses, one should read medication labels carefully for the presence of paracetamol and check with a pharmacist before using over-the-counter medications.

Risk factors for toxicity

Chronic excessive ethanol (alcohol) consumption can induce CYP2E1, thus increasing the potential toxicity of paracetamol.[9] For this reason, other analgesics such as aspirin or ibuprofen are sometimes recommended for hangovers.

Fasting is a risk factor, possibly because of depletion of hepatic glutathione reserves.

It is well documented that concomitant use of the CYP2E1 inducer isoniazid increases the risk of hepatotoxicity, though whether CYP2E1 induction is related to the hepatotoxicity in this case is unclear.[10][11] Concomitant use of other drugs which induce CYP enzymes such as antiepileptics (including carbamazepine, phenytoin, barbituates, etc) have also been reported as risk factors.

Natural history

Individuals who have overdosed on paracetamol generally have no specific symptoms for the first 24 hours. Although nausea, vomiting, and diaphoresis may occur initially, these symptoms generally resolve after several hours. After resolution of these symptoms, individuals tend to feel better, and may believe that the worst is over. If a toxic dose was absorbed, after this brief feeling of relative wellness, the individual develops overt hepatic failure. In massive overdoses, coma and metabolic acidosis may occur prior to hepatic failure.

Damage generally occurs in hepatocytes as they metabolize the paracetamol. Rarely, acute renal failure also may occur. This is usually caused by either hepatorenal syndrome or Multiple organ dysfunction syndrome. Acute renal failure may also be the primary clinical manifestation of toxicity. In these cases, it has been suggested that the toxic metabolite is produced more in the kidneys than in the liver.[12]

The prognosis of paracetamol toxicity varies depending on the dose and the appropriate treatment. In some cases, massive hepatic necrosis leads to fulminant hepatic failure with complications of bleeding, hypoglycemia, renal failure, hepatic encephalopathy, cerebral edema, sepsis, multiple organ failure, and death within days. In many cases, the hepatic necrosis may run its course, hepatic function may return, and the patient may survive with liver function returning to normal in a few weeks.

Diagnosis

Evidence of liver toxicity may develop in 1 to 4 days, although in severe cases it may be evident in 12 hours. Right upper quadrant tenderness may be present. Laboratory studies may show evidence of massive hepatic necrosis with elevated AST, ALT, bilirubin, and prolonged coagulation times (particularly, elevated prothrombin time). After paracetamol overdose, when AST and ALT exceed 1000 IU/L, paracetamol-induced hepatotoxicity can be diagnosed. However, the AST and ALT levels can exceed 10,000 IU/L. Generally the AST is somewhat higher than the ALT in paracetamol-induced hepatotoxicity.

A drug nomogram was developed in 1975 which estimated the risk of toxicity based on the serum concentration of paracetamol at a given number of hours after ingestion.[13] To determine the risk of potential hepatotoxicity, the paracetamol level is traced along the standard nomogram. A paracetamol level drawn in the first four hours after ingestion may underestimate the amount in the system because paracetamol may still be in the process of being absorbed from the gastrointestinal tract. Delay of the initial draw for the paracetamol level to account for this is not recommended since the history in these cases is often poor and a toxic level at any time is a reason to give the antidote.

Treatment

Initial measures

The initial treatment for uncomplicated paracetamol overdose, similar to any other overdose, is gastrointestinal decontamination. In addition, the antidote, acetylcysteine plays an important role. Paracetamol absorption from the gastrointestinal tract is complete within 2 hours under normal circumstances, so decontamination is most helpful if performed within this timeframe. Absorption may be somewhat slowed when it is ingested with food. There is considerable room for physician judgement regarding gastrointestinal decontamination, activated carbon administration is the most commonly used procedure, however, gastric lavage may also be considered if the amount ingested is potentially life threatening and the procedure can be performed within 60 minutes of ingestion.[14] Syrup of ipecac has no role in paracetamol overdose because the vomiting it induces delays the effective administration of activated carbon and oral acetylcysteine.

Activated carbon adsorbs paracetamol, reducing its gastrointestinal absorption. Administering activated carbon also poses less risk of aspiration than gastric lavage. Previously there was reluctance to give activated carbon in paracetamol overdose, because of concern that it may also absorb acetylcysteine. Studies have shown that no more than 39% of an oral acetylcysteine is absorbed when they are administered together.[15] Other studies have shown that activated carbon seems to be beneficial to the clinical outcome. It appears the most benefit from activated carbon is gained if it is given with 2 hours of ingestion.[16] However, administering activated carbon later than this can be considered in patients who may have delayed gastric emptying due to co-ingested drugs or following ingestion of sustained or delayed release paracetamol preparations. Activated carbon should also be administered if co-ingested drugs warrant decontamination. There are conflicting recommendations[15][17] regarding whether to change the dosing of oral acetylcysteine after the administration of activated carbon, and even whether the dosing of acetylcysteine needs to be altered at all.

Acetylcysteine

Acetylcysteine works to reduce paracetamol toxicity by supplying sulfhydryl groups (mainly in the form of glutathione, of which it is a precursor) to react with the toxic NAPQI metabolite so that it does not damage cells and can be safely excreted.

If the patient presents less than 8 hours after paracetamol overdose, then acetylcysteine significantly reduces the risk of serious hepatotoxicity. If NAC is started more than 8 hours after ingestion, there is a sharp decline in its effectiveness because the cascade of toxic events in the liver has already begun and the risk of acute hepatic necrosis and death increases dramatically. Although acetylcysteine is most effective if given early, it still has beneficial effects if given as late as 48 hours after ingestion.[18] In clinical practice, if the patient presents more than 8 hours after the paracetamol overdose, then activated charcoal is probably not useful, and acetylcysteine is started immediately. In earlier presentations the

doctor can give charcoal as soon as the patient arrives, start giving acetylcysteine, and wait for the paracetamol level from the laboratory.

In United States practice, intravenous (IV) and oral administration are considered to be equally effective. However, IV is the only recommended route in Australasian and British practice.

Oral acetylcysteine is given as a 140 mg/kg loading dose followed by 70 mg/kg every 4 hours for 17 more doses. Oral acetylcysteine may be poorly tolerated due to its unpleasant taste, odor, and its tendency to cause nausea and vomiting. It can be diluted to a 5% solution, from its marketed 10% or 20% solutions, to improve palatability. Where oral acetylcysteine is required, the inhalation formulation of acetylcysteine (Mucomyst) is often given orally. The respiratory formulation can also be diluted and filter sterilized by a hospital pharmacist for IV use, however this is an uncommon practice. If repeat doses of charcoal are indicated because of another ingested drug, then subsequent doses of carbon and acetylcysteine should be staggered every two hours.

Intravenous acetylcysteine (Parvolex/Acetadote) is used as a continuous intravenous infusion over 20 hours (total dose 300 mg/kg). Recommended administration involves infusion of a 150 mg/kg loading dose over 15 minutes, followed by 50 mg/kg infusion over 4 hours; the last 100 mg/kg are infused over the remaining 16 hours of the protocol. Intravenous acetylcysteine has the advantage of shortening hospital stay, increasing both doctor and patient convenience, and it allows administration of activated carbon to reduce absorption of both the paracetamol and any co-ingested drugs without concerns about interference with oral acetylcysteine.[19]

Baseline laboratory studies include bilirubin, AST, ALT, and prothrombin time (with INR). Studies are repeated at least daily. Once it has been determined that a potentially toxic overdose has occurred, acetylcysteine is continued for the entire regimen, even after the paracetamol level becomes undetectable in the blood. If hepatic failure develops, acetylcysteine should be continued beyond the standard doses until hepatic function improves or until the patient has a liver transplant.

Prognosis

The mortality rate from paracetamol overdose increases 2 days after the ingestion, reaches a maximum on day 4, and then gradually decreases. Patients with a poor prognosis are usually identified for likely liver transplantation. Acidemia is the most important single indicator of probable mortality and the need for transplantation. A mortality rate of 95% without transplant was reported in patients who had a documented pH of < 7.30. Other indicators of poor prognosis include renal insufficiency, grade 3 or worse hepatic encephalopathy, a markedly elevated prothrombin time, or a rise in prothrombin time from day 3 to day 4. One study has shown that a factor V level less than 10% of normal indicated a poor prognosis (91% mortality) while a ratio of factor VIII to factor V of less than 30 indicated a good prognosis (100% survival).

Danger to animals

Paracetamol is extremely toxic to cats, and should not be given to them under any circumstances. Cats lack the necessary glucuronyl transferase enzymes to safely break paracetamol down and tiny fractions of a normal tablet for humans may prove fatal.[20]

In dogs paracetamol is a useful anti-inflammatory with a good safety record, causing a lower incidence of gastric ulceration than NSAIDs. It should only be administered on veterinary advice. A paracetamol codene product (Pardale-V)[2] licensed for use in dogs is available on veterinary prescription in the UK.

Any cases of suspected ingestion in cats or overdose in dogs should be taken to a veterinarian immediately for detoxification.[21] The effects of toxicity can include liver damage, haemolytic anaemia, oxidative damage to the red blood cells and bleeding tendencies. There are no home remedies, and the amount of irreversible liver failure is dependent on how quickly veterinary intervention begins. Treatment of paracetamol overdose by a veterinarian may involve the use of supportive fluid therapy, acetylcysteine (Mucomyst), methionine or s-adenosyl-l-methionine (SAMe) to slow liver damage and cimetidine (Tagamet) to protect against gastric ulceration. Once liver damage has occurred it cannot be reversed.[3]

November 2006 United States recall of generic paracetamol

On November 9, 2006, the U.S. Food and Drug Administration (FDA) announced a recall of approximately 11 million bottles of generic paracetamol manufactured by Perrigo, the largest manufacturer of generic over-the-counter drugs in the United States, due to metal particles having been found in a small sample of paracetamol caplets.[22] The recall is limited to 383 lots of 500 mg caplets; other lots and other dosages, as well as generic paracetamol from other manufacturers or proprietary formulations of paracetamol, are not affected. The complete list of recalled lots may be found on the FDA website.

As of November 14, 2006, no deaths or injuries have been reported as a result of the incident.

Anaesthetics

A wide variety of drugs are used in modern anaesthetic practice. Many are rarely used outside of anaesthesia, although others are used commonly by all disciplines. Some of the prominent ones include:

- local anaesthetics
  - general anaesthetics
    - inhalational anaesthetics
      - volatile anaesthetics
        - desflurane

sevoflurane
isoflurane
halothane
enflurane
methoxyflurane

- nitrous oxide
  - xenon
- intravenous anaesthetics
  - propofol

etomidate

- barbiturates
  - methohexital

thiopentone/thiopental

- benzodiazepines
  - midazolam
  - diazepam
- ketamine

- analgesics
  - opioids
    - morphine
    - fentanyl

- alfentanil
sufentanil
remifentanil

- methadone

- meperidine / pethidine
- NSAIDs

- muscle relaxants
  - depolarising muscle relaxants
    - succinylcholine, also known as suxamethonium
  - nondepolarising (curare-like) muscle relaxants
    - atracurium
cisatracurium
vecuronium
rocuronium
mivacurium
tubocurarine (see mislabelled article "turbocurnanine" under "search." Can this article be placed correctly under tubocurarine also?)
pancuronium bromide
- vasoconstrictors, also known as vasopressors
  - phenylephrine
  - Ephedrine
  - metaraminol
- antiemetics: phenothiazines, e.g.: prochlorperazine, promethazine, cyclizine;

butyrophenones, e.g.: droperidol; antihistamines, e.g.: dimenhydrinate (old); newer agents: ondansetron and tropisetron, and granisetron; steroids, e.g.: dexamethasone; and lastly, metoclopramide (variable efficacy).

Local anesthetics

A *local anesthetic* is a drug that reversibly inhibits the propagation of signals along nerves. When it is used on specific nerve pathways, effects such as analgesia (loss of pain sensation) and paralysis (loss of muscle power) can be achieved.

Clinical local anesthetics belong to one of two classes: aminoamide and aminoester local anesthetics. These so-called synthetic local anesthetics are structurally related to cocaine. They differ from cocaine mainly in that they have no abuse potential and do not act on the sympathoadrenergic system, i.e. they do not produce hypertension or local vasoconstriction.

Local anesthetics vary in their pharmacological properties and they are used in various techniques of local anesthesia such as:

- Topical anesthesia (surface)
- Infiltration
- Plexus block
- Epidural (extradural) block
- Spinal anesthesia

The local anesthetic lidocaine is also used as a Class Ib antiarrhythmic drug.

Mechanism of action

Local anesthetic drugs act mainly by inhibiting sodium influx through sodium-specific ion channels in the neuronal cell membrane, in particular the so-called voltage-gated sodium channels. When the influx of sodium is interrupted, an action potential cannot arise and signal conduction is inhibited. The receptor site is thought to be located at the cytoplasmic (inner) portion of the sodium channel. Local anesthetic drugs bind more readily to "open" sodium channels, thus onset of neuronal blockade is faster in neurons that are rapidly firing. This is referred to as state dependent blockade.

Local anesthetics are weak bases and are usually formulated as the hydrochloride salt to render them water-soluble. At physiologic pH the protonated (ionised) and unprotonated (unionised) forms of the molecule exist in an equilibrium but only the unprotonated molecule diffuses readily across cell membranes. Once inside the cell, the lower pH results in the molecule being protonated, thus inhibiting its passage back out of the cell. This is referred to as "ion-trapping". In the protonated form, the molecule binds to the local anaesthetic binding site on the inside of the ion channel near the cytoplasmic end.

Acidosis such as caused by wound infection partly reduces the action of local anesthetics. This is partly because most of the anaesthetic is ionised and therefore unable to cross the cell membrane.

Undesired effects

The conduction of electric impulses follows a similar mechanism in peripheral nerves, the central nervous system, and the heart. The effects of local anesthetics are therefore not specific for the signal conduction in peripheral nerves. Side effects on the central nervous system and the heart may be severe and potentially fatal. However, toxicity usually occurs only at blood plasma levels which are rarely reached if proper anesthetic techniques are adhered to.

Central nervous system

Depending on local tissue concentrations of local anesthetics, there may be excitatory or depressant effects on the central nervous system. At lower concentrations, a relatively selective depression of inhibitory neurons results in cerebral excitation, which may lead to generalized convulsions. A profound depression of brain functions occurs at higher concentrations which may lead to coma, respiratory arrest and death. Such tissue concentrations may be due to very high plasma levels after intravenous injection of a large

dose. Another possibility is direct exposure of the central nervous system through the cerebrospinal fluid, i.e. overdose in spinal anesthesia or accidental injection into the subarachnoid space in epidural anesthesia.

Cardiovascular system

The conductive system of the heart is quite sensitive to the action of local anesthetics. Lidocaine is often used as an antiarrhythmic drug and has been studied extensively, but the effects of other local anesthetics are probably similar to those of Lidocaine. Lidocaine acts by blocking sodium channels, leading to slowed conduction of impulses. This may obviously result in bradycardia, but tachyarrhythmia can also occur. With high plasma levels of lidocaine there may be higher-degree atrioventricular block and severe bradycardia, leading to coma and possibly death.

Treatment of overdose

There is evidence that Intralipid, a commonly available intravenous lipid emulsion, can be effective in treating severe cardiotoxicity secondary to local anaesthetic overdose, including human case reports of successful use in this way ('lipid rescue').[1][2][3]

Hypersensitivity/Allergy

Adverse reactions to local anesthetics are not infrequent, but true allergy is very rare. Non-allergic reactions may resemble allergy in their manifestations. In some cases, skin tests and provocative challenge may be necessary to establish a diagnosis of allergy. There are also cases of allergy to paraben derivatives, which are often added as preservatives to local anesthetic solutions.

Methemoglobinemia

The systemic toxicity of prilocaine is comparatively low, however its metabolite, o-toluidine, is known to cause methemoglobinemia. As methemoglobinemia reduces the amount of hemoglobin that is available for oxygen transport, this side effect is potentially life-threatening. Therefore dose limits for prilocaine should be strictly observed. Prilocaine is not recommended for use in infants.

Local anesthetics in clinical use

- Amino esters
  - Benzocaine
  - Chloroprocaine
  - Cocaine
  - Procaine
- Amino amides
  - Bupivacaine
  - Levobupivacaine
  - Lidocaine
  - Mepivacaine
  - Prilocaine
  - Ropivacaine
- Combinations
  - Lidocaine/prilocaine (EMLA)

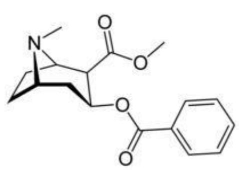
Cocaine



Systematic (IUPAC) name

methyl (1R,2R,3S,5S)-3-(benzoyloxy)-8-methyl-8-azabicyclo[3.2.1]octane-2-carboxylate

Identifiers

CAS number 50-36-2

ATC code N01**BC01** R02**AD03**, S01**HA01**, S02**DA02**

PubChem 5760

DrugBank APRD00080

Chemical data

Formula $C_{17}H_{21}NO_4$

Mol. weight 303.353 g/mol

Physical data

Melt. point 195 °C (383 °F)

Solubility in water 1800 mg/mL (20 °C)

Pharmacokinetic data

Bioavailability Oral: 30%, Nasal: 30-60% [1]

Metabolism Hepatic CYP3A4

Half life 1 hour

Excretion Renal (benzoylecgonine and ecgonine methyl ester)

Therapeutic considerations

Pregnancy cat. C

Legal status Schedule I(CA) Class A(UK) Schedule II(US)

Dependence Liability Medium

Routes Topical, Oral, Insufflation, IV, PO

Cocaine is a crystalline tropane alkaloid that is obtained from the leaves of the coca plant. It is a stimulant of the central nervous system and an appetite suppressant, creating what has been described as a euphoric sense of happiness and increased energy. Though most often used recreationally for this effect, cocaine is also a topical anesthetic used in eye, throat, and nose surgery. Cocaine can be psychologically addictive, and its possession, cultivation, and distribution is illegal for non-medicinal and non-government sanctioned purposes in virtually all parts of the world. The name comes from the name of the coca plant plus the alkaloid suffix -ine.

The stimulating qualities of the coca leaf were known to the ancient peoples of Peru and other Pre-Columbian South American societies. In modern Western countries, cocaine has been a feature of the counterculture for well-over a century; there is a long-list of prominent intellectuals, artists, and musicians who have used the drug — names ranging from Sir Arthur Conan Doyle and Sigmund Freud to United States President Ulysses S. Grant. For several decades after its initial release, cocaine could be found in trace amounts in the Coca-Cola beverage. Today, although illegal in virtually all countries, cocaine remains popular in a wide variety of social and personal settings.

History

The coca leaf

South American indigenous peoples have chewed the coca leaf (Erythroxylum coca), a plant that contains vital nutrients as well as numerous alkaloids, including cocaine. The leaf

was, and is, chewed almost universally by some indigenous communities—ancient Peruvian mummies have been found with the remains of coca leaves deposited in their mouths, and pottery from the time period depicts humans whose cheeks are bulged with the presence of something on which they are chewing.[2]However, it should be noted that there is no evidence that its habitual use has ever led to any of the negative consequences generally associated with habitual cocaine use today.[3][4] There is evidence that these cultures used a mixture of coca leaves and saliva as an anesthetic for the performance of trepanation.[5]

When the Spaniards colonized South America, they at first ignored aboriginal claims that the leaf gave them strength and energy, and declared the chewing of coca leaves a satanic practice. But after discovering that these claims were true, they legalized and taxed the leaf, taking 10 percent off the value of each crop. These taxes were for a time the main source of support for the Roman Catholic Church in the region. In 1569, Nicholas Monardes described the practice of the natives of chewing a mixture of tobacco and coca leaves to induce "great contentment":

"[...when they wished to] make themselves drunk and [...] out of judgment [they chewed a mixture of tobacco and coca leaves which...] make them go as they were out of their wittes [...]"

[6]

In 1609, Padre Blas Valera wrote:

"Coca protects the body from many ailments, and our doctors use it in powdered form to reduce the swelling of wounds, to strengthen broken bones, to expel cold from the body or prevent it from entering, and to cure rotten wounds or sores that are full of maggots. And if it does so much for outward ailments, will not its singular virtue have even greater effect in the entrails of those who eat it?"

Isolation

Although the stimulant and hunger-suppressant properties of coca had been known for many centuries, the isolation of the cocaine alkaloid was not achieved until 1855. Many scientists had attempted to isolate cocaine, but none had been successful for two reasons: the knowledge of chemistry required was insufficient at the time, worsened because coca does not grow in Europe and ruins easily during travel.

The cocaine alkaloid was first isolated by the German chemist Friedrich Gaedcke in 1855. Gaedcke named the alkaloid “erythroxyline,” and published a description in the journal Archives de Pharmacie.

In 1856, Friedrich Wöhler asked Dr. Carl Scherzer, a scientist aboard the Novara (an Austrian frigate sent by Emperor Franz Joseph to circle the globe), to bring him a large amount of coca leaves from South America. In 1859, the ship finished its travels and Wöhler received a trunk full of coca. Wöhler passed on the leaves to Albert Niemann, a Ph.D. student at the University of Göttingen in Germany, who then developed an improved purification process.

Niemann described every step he took to isolate cocaine in his dissertation titled Über eine neue organische Base in den Cocablättern (On a New Organic Base in the Coca Leaves), which was published in 1860—it earned him his Ph. D. and is now in the British Library. He wrote of the alkaloid's “colourless transparent prisms” and said that, “Its solutions have an alkaline reaction, a bitter taste, promote the flow of saliva and leave a peculiar numbness, followed by a sense of cold when applied to the tongue.” Niemann named the alkaloid “Cocain”—as with other alkaloids its name carried the “-in” ending (derived from the Latin suffix -ina).

Medicalization

With the discovery of this new alkaloid, Western medicine was quick to jump upon and exploit the possible uses of this plant.

In 1879, Vassili von Anrep, of the University of Würzburg, devised an experiment to demonstrate the analgesic properties of the newly-discovered alkaloid. He prepared two separate jars, one containing a cocaine-salt solution, with the other containing merely salt water. He then submerged a frog's legs into the two jars, one leg in the treatment and one in the control solution, and proceeded to stimulate the legs in several different ways. The leg that had been immersed in the cocaine solution reacted very differently than the leg that had been immersed in salt water.[7]

Carl Koller (a close associate of Sigmund Freud, who would write about cocaine later) experimented with cocaine for ophthalmic usage. In an infamous experiment in 1884, he experimented upon himself by applying a cocaine solution to his own eye and then pricking it with pins. His findings were presented to the Heidelberg Ophthalmological Society. Also in 1884, Jellinek demonstrated the effects of cocaine as a respiratory system anesthetic. In 1885, William Halsted demonstrated nerve-block anesthesia,[8] and James Corning demonstrated peridural anesthesia.[9] 1898 saw Heinrich Quincke use cocaine for spinal anesthesia.

Popularization

In 1859, an Italian doctor, Paolo Mantegazza returned from Peru, where he had witnessed first-hand the use of coca by the natives. He proceeded to experiment on himself and upon his return to Milan he wrote a paper in which he described the effects. In this paper he declared coca and cocaine (at the time they were assumed to be the same) as being useful medicinally, in the treatment of “a furred tongue in the morning, flatulence, [and] whitening of the teeth.”

A chemist named Angelo Mariani who read Mantegazza’s paper became immediately intrigued with coca and its economic potential. In 1863, Mariani started marketing a wine called Vin Mariani, which had been treated with coca leaves. The ethanol in wine acted as a solvent and extracted the cocaine from the coca leaves, altering the drink’s effect. It contained 6 mg cocaine per ounce of wine, but Vin Mariani, which was to be exported, contained 7.2 mg per ounce to compete with the higher cocaine content of similar drinks in the United States. A “pinch of coca leaves” was included in John Styth Pemberton's original

1886 recipe for Coca-Cola, though the company began using decocainized leaves in 1906 when the Pure Food and Drug Act was passed. The only known measure of the amount of cocaine in Coca-Cola was determined in 1902 as being as little as 1/400 of a grain (0.2 mg) per ounce of syrup (6 ppm). The actual amount of cocaine that Coca-Cola contained during the first twenty years of its production is practically impossible to determine.

In 1879 cocaine began to be used to treat morphine addiction. Cocaine was introduced into clinical use as a local anaesthetic in Germany in 1884, about the same time as Sigmund Freud published his work Über Coca (On Coca), in which he wrote that cocaine causes:

"...exhilaration and lasting euphoria, which in no way differs from the normal euphoria of the healthy person...You perceive an increase of self-control and possess more vitality and capacity for work....In other words, you are simply normal, and it is soon hard to believe you are under the influence of any drug....Long intensive physical work is performed without any fatigue...This result is enjoyed without any of the unpleasant after-effects that follow exhilaration brought about by alcohol....Absolutely no craving for the further use of cocaine appears after the first, or even after repeated taking of the drug..."

In 1885 the U.S. manufacturer Parke-Davis sold cocaine in various forms, including cigarettes, powder, and even a cocaine mixture that could be injected directly into the user's veins with the included needle. The company promised that its cocaine products would "supply the place of food, make the coward brave, the silent eloquent and... render the sufferer insensitive to pain."

By the late Victorian era cocaine use had appeared as a vice in literature; for example, Arthur Conan Doyle's fictional Sherlock Holmes injects a "seven-percent solution" of the drug in The Sign of Four.

In 1909, Ernest Shackleton took "Forced March" brand cocaine tablets to Antarctica, as did Captain Scott a year later on his ill-fated journey to the South Pole.[10] Even as late as 1938, the Larousse Gastronomique was published carrying a recipe for "cocaine pudding".

Prohibition

By the turn of the twentieth century, the addictive properties of cocaine had become clear to many, and the problem of cocaine abuse began to capture public attention in the United States. The dangers of cocaine abuse became part of a moral panic that was tied to the dominant racial and social anxieties of the day. In 1903, the American Journal of Pharmacy stressed that most cocaine abusers were "bohemians, gamblers, high- and low-class prostitutes, night porters, bell boys, burglars, racketeers, pimps, and casual laborers." In 1914, Dr. Christopher Koch of Pennsylvania's State Pharmacy Board made the racial innuendo explicit, testifying that, "Most of the attacks upon the white women of the South are the direct result of a cocaine-crazed Negro brain."[citation needed] Mass media created an epidemic of cocaine use among African Americans in the Southern United States to play upon racial prejudices of the era, though there is little evidence that such an epidemic actually took place. In the same year, the Harrison Narcotics Tax Act outlawed the use of cocaine in the United States. This law incorrectly referred to cocaine as a narcotic, and the

misclassification passed into popular culture. As stated above, cocaine is a stimulant, not a narcotic.

Modern usage

In many countries, cocaine is a popular recreational drug. In the United States, the development of "crack" cocaine introduced the substance to a generally poorer inner-city market. Use of the powder form has stayed relatively constant, experiencing a new height of use during the late 1990's, however, use has dropped somewhat from the early 2000's giving way to MDMA which has increased in popularity. Cocaine has become much more popular in the last few years in the UK.

Cocaine use is prevalent across all socioeconomic strata, including age, demographics, economic, social, political, religious, and livelihood. Cocaine in its various forms comes in second only to cannabis as the most popular illegal recreational drug in the United States, and is number one in street value sold each year.

The estimated U.S. cocaine market exceeded $35 billion in street value for the year 2003. There is a tremendous demand for cocaine in the U.S. market, particularly among those who are making incomes affording luxury spending, such as single adults and various professionals. Cocaine's status as a club drug shows its immense popularity among the "party crowd."

In 1995 the World Health Organization (WHO) and the United Nations Interregional Crime and Justice Research Institute (UNICRI) announced in a press release the publication of the results of the largest global study on cocaine use ever undertaken. However, a decision in the World Health Assembly banned the publication of the study. In the sixth meeting of the B committee the US representative threatened that "If WHO activities relating to drugs failed to reinforce proven drug control approaches, funds for the relevant programmes should be curtailed". This led to the decision to discontinue publication. A part of the study has been recuperated.[11] Available are profiles of cocaine use in 20 countries. Some of the findings were that "Generally cocaine users consume a range of other drugs as well. There appears to be very little 'pure' cocaine use. Overall, fewer people in participating countries have used cocaine than have used alcohol, tobacco or cannabis. Also, in most countries, cocaine is not the drug associated with the greatest problems.", "There is a complex relationship between cocaine use and crime, particularly theft and violence.", "In most participating countries, a minority of people start using cocaine or related products, use casually for a short or long period, and suffer little or no negative consequences, even after years of use. This suggests it is possible to reduce, if not entirely eliminate, harmful cocaine use."[12]

A problem with illegal cocaine use, especially in the higher volumes used to combat fatigue (rather than increase euphoria) by long-term users is trauma caused by the compounds used in adulteration. Cutting or "stamping on" the drug is commonplace, using compounds which simulate ingestion effects, such as novocaine producing temporary anasthaesia, ephedrine producing an increased heart rate, or more dangerously, strong toxins to produce vasodilatory effects. For example a nosebleed is foolishly regarded by heavy users as a sign of purity. The normal adulterants for profit are inactive sugars, usually mannitol, creatine or glucose, so introducing active adulterants gives the illusion of purity. Cocaine trading carries large penalties in most jurisdictions, so user deception about purity and consequent high profits for dealers are the norm.

Pharmacology

Appearance

Cocaine in its purest form is a white, pearly product. Cocaine appearing in powder form is a salt, typically cocaine hydrochloride (CAS 53-21-4). Black market cocaine is frequently adulterated or "cut" with various powdery fillers to increase its surface area; the substances most commonly used in this process are baking soda; sugars, such as lactose, dextrose, inositol, and mannitol; and local anesthetics, such as lidocaine or benzocaine, which mimic or add to cocaine's numbing effect on mucous membranes. Cocaine may also be "cut" with other stimulants such as methamphetamine. Adulterated cocaine is often a white, off-white or pinkish powder. Novacaine, a dental anesthetic and benzocaine (an ingredient used in Anbesol and other non-prescription oral anesthetics) are related to cocaine and can both cause a person to test positive for it even though they are not using illegal drugs.

The color of "crack" cocaine depends upon several factors including the origin of the cocaine used, the method of preparation – with ammonia or sodium bicarbonate – and the presence of impurities, but will generally range from white to a yellowish creme to a light brown. Its texture will also depend on the adulterants, origin and processing of the powdered cocaine, and the method of converting the base; but will range from a crumbly texture, sometimes extremely oily, to a hard, almost crystalline nature.

Forms of cocaine

Cocaine sulfate

Cocaine sulfate is produced by macerating coca leaves along with water that has been acidulated with sulfuric acid, or a aromatic-based solvent, like kerosene or benzene. This is often accomplished by putting the ingredients into a vat and stamping on it, in a manner similar to the traditional method for crushing grapes. After the cocaine is extracted, the water is evaporated to yield a pasty mass of impure cocaine sulfate.

The sulfate itself is an intermediate step to producing cocaine hydrochloride. In South America, it is commonly smoked along with tobacco, and is known as pasta, basuco, basa, pitillo, paco or simply paste. It is also gaining popularity as a cheap drug (.30-.70 U.S. cents per "hit" or dose) in Argentina.

Freebase

As the name implies, "freebase" is the base form of cocaine, as opposed to the salt form of cocaine hydrochloride. Whereas cocaine hydrochloride is extremely soluble in water, cocaine base is insoluble in water and is therefore not suitable for drinking, snorting or injecting. Cocaine hydrochloride is not well-suited for smoking because the temperature at

which it vaporizes is very high, and close to the temperature at which it burns; however, cocaine base vaporizes at a low temperature, which makes it suitable for inhalation.

Smoking freebase is preferred by many users because the cocaine is absorbed immediately into blood via the lungs, where it reaches the brain in about five seconds. The rush is much more intense than sniffing the same amount of cocaine nasally, but the effects do not last as long. The peak of the freebase rush is over almost as soon as the user exhales the vapor, but the high typically lasts 5–10 minutes afterward. What makes freebasing particularly dangerous is that users typically don't wait that long for their next hit and will continue to smoke freebase until none is left. These effects are similar to those that can be achieved by injecting or “slamming” cocaine hydrochloride, but without the risks associated with intravenous drug use (though there are other serious risks associated with smoking freebase).

Freebase cocaine is produced by first dissolving cocaine hydrochloride in water. Once dissolved in water, cocaine hydrochloride (Coc HCl) dissociates into protonated cocaine ion (Coc-H+) and chloride ion (Cl–). Any solids that remain in the solution are not cocaine (they are part of the cut) and are removed by filtering. A base, typically ammonia (NH3), is added to the solution. The following net chemical reaction takes place:

$$\text{Coc-H}^{+}\text{Cl}^{-} + \text{NH}_3 \rightarrow \text{Coc} + \text{NH}_4\text{Cl}$$

As freebase cocaine (Coc) is insoluble in water, it precipitates and the solution becomes cloudy. To recover the freebase, a nonpolar solvent like diethyl ether is added to the solution: Because freebase is highly soluble in ether, a vigorous shaking of the mixture results in the freebase being dissolved in the ether. As ether is insoluble in water, it can be siphoned off. The ether is then evaporated, leaving behind the cocaine base.

Handling diethyl ether is dangerous because ether is extremely flammable, its vapors are heavier than air and can “creep” from an open bottle, and in the presence of oxygen it can form peroxides, which can spontaneously combust. Demonstrative of the dangers of the practice, the famous comedian Richard Pryor used to perform a well known skit in which he poked fun at himself over a 1980 incident in which he caused an explosion and set himself on fire while attempting to smoke “freebase”, presumably while still wet with ether.

Crack cocaine

Due to the dangers of using ether to produce pure freebase cocaine, cocaine producers began to omit the step of removing the freebase cocaine precipitate from the ammonia mixture. Typically, filtration processes are also omitted. The end result of this process is that the cut, in addition to the ammonium salt (NH_4Cl), remains in the freebase cocaine after the mixture is evaporated. The “rock” that is thus formed also contains a small amount of water. Sodium bicarbonate is also preferred in preparing the freebase, for when commonly "cooked" the ratio is 50/50 to 40/60 percent cocaine/bicarbonate. This acts as a filler which extends the overall profitability of illicit sales. Crack cocaine may be reprocessed in small quantities with water (users refer to the resultant product as "cookback"). This removes the

residual bicarbonate, and any adulterants or cuts that have been used in the previous handling of the cocaine and leaves a relatively pure, anhydrous cocaine base.

When the rock is heated, this water boils, making a crackling sound (hence the onomatopoeic “crack”). Baking soda is now most often used as a base rather than ammonia for reasons of lowered stench and toxicity; however, any weak base can be used to make crack cocaine. Strong bases, such as sodium hydroxide, tend to hydrolyze some of the cocaine into non-psychoactive ecgonine.

The net reaction when using baking soda (also called sodium bicarbonate, with a chemical formula of $NaHCO_3$) is:

$$Coc\text{-}H^+Cl^- + NaHCO_3 \rightarrow Coc + H_2O + CO_2 + NaCl$$

Crack is unique because it offers a strong cocaine experience in small, low-priced packages. In the United States, crack cocaine is often sold in small, inexpensive dosage units frequently known as “nickels”, “nickel rocks”, or "bumps" (referring to the price of $5.00), and also “dimes”, “dime rocks”, or "boulders" and sometimes as “twenties”, “solids", "slabs" and “forties.” The quantity provided by such a purchase varies depending upon many factors, such as local availability, which is affected by geographic location. A twenty may yield a quarter gram or half gram on average, yielding 30 minutes to an hour of effect if hits are taken every few minutes. After the $20 or $40 mark, crack and powder cocaine are sold in grams or fractions of ounces. At the intermediate level, crack cocaine is sold either by weight in ounces, referred to by terms such as "eight-ball" (one-eighth of an ounce) or "quarter" and "half" respectively. In the alternate, $20 pieces of crack cocaine are aggregated in units of "fifty pack" and "hundred pack", referring to the number of pieces. At this level, the wholesale price is approximately half the street sale price.

Crack cocaine was extremely popular in the mid- and late 1980s in a period known as the Crack Epidemic, especially in inner cities, though its popularity declined through the 1990s in the United States. There were major anti-drug campaigns launched in the U.S. to try and cull its popularity, the most popular being a series of ads featuring the slogan "The Thrill Can Kill".[13] However, there has been an increase in popularity within Canada in the recent years, where it has been estimated that the drug has become a multi-billion dollar 'industry'. Due to its popularity, there are many different street names for crack cocaine.

Although consisting of the same active drug as powder cocaine, crack cocaine in the United States is seen as a drug primarily by and for the inner-city poor; the stereotypical "crack head" is a poor, urban, usually homeless. While insufflated powder cocaine has an associated glamour attributed to its popularity among mostly middle and upper class whites (as well as musicians and entertainers), crack is perceived as a skid row drug of squalor and desperation. The U.S. federal trafficking penalties deal far more harshly towards crack when compared to powdered cocaine. Possession of five grams of crack (or over 500 grams of powder) carries a minimum sentence of five years imprisonment in the US.[14]

Modes of administration

Chewed/eaten

Coca leaves typically are mixed with an alkaline substance (such as lime) and chewed into a wad that is retained in the mouth between gum and cheek and sucked of its juices. The juices are absorbed slowly by the mucous membrane of the inner cheek and by the gastro-intestinal tract when swallowed. Alternatively, coca leaves can be infused in liquid and consumed like tea. Ingesting coca leaves generally is an inefficient means of administering cocaine. It should be remembered that the coca leaf is not actual cocaine, and is not a drug of any kind. Because cocaine is hydrolyzed (rendered inactive) in the acidic stomach, it is not readily absorbed. Only when mixed with a highly alkaline substance (such as lime) can it be absorbed into the bloodstream through the stomach. Absorption of orally administered cocaine is limited by two additional factors. First, the drug is partly metabolized in the liver. Second, capillaries in the mouth and esophagus constrict after contact with the drug, reducing the surface area over which the drug can be absorbed.

Orally administered cocaine takes approximately 30 minutes to enter the bloodstream. Typically, only 30 percent of an oral dose is absorbed, although absorption has been shown to reach 60 percent in controlled settings. Given the slow rate of absorption, maximum physiological and psychotropic effects are attained approximately 60 minutes after cocaine is administered by ingestion. While the onset of these effects is slow, the effects are sustained for approximately 60 minutes after their peak is attained.

Contrary to popular belief, both ingestion and insufflation result in approximately the same proportion of the drug being absorbed: 30 to 60 percent. G. Barnett, R. Hawks and R. Resnick, "Cocaine Pharmacokinetics in Humans," 3 Journal of Ethnopharmacology 353 (1981); Jones, supra note 19; Wilkinson et al., Van Dyke et al., Compared to ingestion, the faster absorption of insufflated cocaine results in quicker attainment of maximum drug effects. Snorting cocaine produces maximum physiological effects within 40 minutes and maximum psychotropic effects within 20 minutes, However a more realistic activation period is closer to 5 to 10 minutes, which is similar to ingestion of cocaine. Physiological and psychotropic effects from nasally insufflated cocaine are sustained for approximately 40 - 60 minutes after the peak effects are attained. Van Dyke, et al.

Mate de coca or coca-leaf tea is also a traditional method of consumption and is often recommended to treat altitude sickness. This method of consumption has been practiced for thousands of years by South American natives. One specific purpose of ancient coca leaf consumption was to increase energy and reduce fatigue in messengers who made multi-day quests to other settlements.

In 1986 an article in the Journal of the American Medical Association revealed that health food stores were selling coca-leaf tea as “Health Inca Tea.”[15] While the packaging claimed it had been “decocainized,” no such process had taken place—they were selling a controlled substance off the shelves. The article stated that drinking two cups of the tea per day gave a mild stimulation, increased heart rate, and mood elevation, and the tea was essentially harmless. Despite this, the DEA seized several shipments in Hawaii, Chicago, Illinois, Georgia,

and several locations on the East Coast of the United States, and the product was removed from the shelves.[10]

Insufflation

Insufflation (known colloquially as “snorting," “sniffing," or "blowing") is the most common method of ingestion of recreational powder cocaine in the Western world. Contrary to widespread belief, cocaine is not actually inhaled using this method; rather the drug coats and is absorbed through the mucous membranes lining the sinuses. When insufflating cocaine, absorption through the nasal membranes is approximately 30-60 percent, with higher doses leading to increased absorption efficiency. Any material not directly absorbed through the mucous membranes is collected in mucus and swallowed (this "drip" is considered pleasant by some and unpleasant by others). In a study[16] of cocaine users, the average time taken to reach peak subjective effects was 14.6 minutes. Chronic use results in ongoing rhinitis and necrosis of the nasal membranes. Many users report a burning sensation in the nares (nostrils) after cocaine's anasthetic effects wear off. Any damage to the inside of the nose is because cocaine highly constricts blood vessels — and therefore blood & oxygen/nutrient flow-- to that area. If this restriction of adequate blood supply is bad enough and, especially prolonged enough, the tissue there can die.

Prior to insufflation, cocaine powder must be divided into very fine particles. Cocaine of high purity breaks into fine dust very easily, except when it is moist (not well stored) and forms “chunks,” which reduces the efficiency of nasal absorption.

Rolled up banknotes, hollowed-out pens, cut straws, pointed ends of keys, and specialized spoons are often used to insufflate cocaine. Such devices are often referred to as "tooters" by users. The cocaine typically is poured onto a flat, hard surface (such as a mirror) and divided into "lines", which are then insufflated. The amount of cocaine in a line varies widely from person to person and occasion to occasion (the purity of the cocaine is also a factor), but one line is generally considered to be a single dose and is typically 35mg-100mg. However as tolerance builds rapidly in the short-term (hours), many lines are often snorted to produce greater effects.

Injected

Drug injection provides the highest blood levels of drug in the shortest amount of time. Upon injection, cocaine reaches the brain in a matter of seconds, and the exhilarating rush that follows can be so intense that it induces some users to vomit uncontrollably. In a study[16] of cocaine users, the average time taken to reach peak subjective effects was 3.1 minutes. The euphoria passes quickly. Aside from the toxic effects of cocaine, there is also danger of circulatory emboli from the insoluble substances that may be used to cut the drug. There is also a risk of serious infection associated with the use of contaminated needles.

An injected mixture of cocaine and heroin, known as “speedball” or “moonrock”, is a particularly popular and dangerous combination, as the converse effects of the drugs actually complement each other, but may also mask the symptoms of an overdose. It has

been responsible for numerous deaths, particularly in and around Los Angeles, including celebrities such as John Belushi, Chris Farley, Layne Staley and River Phoenix. Experimentally, cocaine injections can be delivered to animals such as fruit flies to study the mechanisms of cocaine addiction.[17]

Smoked

Smoking freebase or crack cocaine is most often accomplished using a pipe made from a small glass tube about one quarter-inch (about 6 mm) in diameter and on the average, four inches long. These are sometimes called "stems", "horns", "blasters" and "straight shooters," readily available in convenience stores or smoke shops. They will sometimes contain a small paper flower and are promoted as a romantic gift. Buyers usually ask for a "rose" or a "flower." An alternate method is to use a small length of a radio antenna or similar metal tube. To avoid burning the user's fingers and lips on the metal pipe, a small piece of paper or cardboard (such as a piece torn from a matchbook cover) is wrapped around one end of the pipe and held in place with either a rubber band or a piece of adhesive tape. A popular (usually pejorative) term for crack pipes is "glass dick."

A small piece (approximately one inch) of heavy steel or copper scouring pad — often called a "brillo" or "chore", from the scouring pads of the same name — is placed into one end of the tube and carefully packed down to approximately three-quarter inch. Prior to insertion, the "brillo" is burnt off, to remove any oily coatings that may be present. It then serves as a reduction base and flow modulator in which the "rock" can melt and boil to vapor.

Another option is to use a deep socket, say 12mm, wrapped with electrical tape. Instead of Chore Boy, users typically employ high grade (very fine) speaker wire rolled into a ball as the filter medium. A Zippo lighter is recommended because of the stronger flame, but the taste of butane is quite noticeable. However, the socket is practically indestructible and inconspicuous.

The "rock" is placed at the end of the pipe closest to the filter and the other end of the pipe is placed in the mouth. A flame from a cigarette lighter or handheld torch is then held under the rock. As the rock is heated, it melts and burns away to vapor, which the user inhales as smoke. The effects, felt almost immediately after smoking, are very intense and do not last long — usually five to fifteen minutes. In a study[16] of cocaine users, the average time taken to reach peak subjective effects was 1.4 minutes. Most users will want more after this time, especially frequent users. "Crack houses" depend on these cravings by providing users a place to smoke, and a ready supply of small bags for sale.

A heavily used crackpipe tends to fracture at the end from overheating with the flame used to heat the crack as the user attempts to inhale every bit of the drug on the metal wool filter. The end is often broken further as the user "pushes" the pipe. "Pushing" is a technique used to partially recover crack that hardens on the inside wall of the pipe as the pipe cools. The user pushes the metal wool filter through the pipe from one end to the other to collect the build-up inside the pipe, which is a very pure and potent form of the base. The ends of the pipe can be broken by the object used to push the filter, frequently a small screwdriver or stiff piece of wire. The user will often remove the most jagged edges and continue using the pipe until it becomes so short that it burns the lips and fingers. To continue using the

pipe, the user will sometimes wrap a small piece of paper or cardboard around one end and hold it in place with a rubber band or adhesive tape. Of course, not all people who smoke crack cocaine will let it get that short, and will get a new or different pipe. The tell-tale signs of a used crack pipe are a glass tube with burn marks at one or both ends and a clump of metal wool inside. The language used to refer to the paraphernalia and practices of smoking cocaine vary tremendously across regions of the United States, as do the packaging methods utilized in the street level sale.

When smoked, cocaine is sometimes combined with other drugs, such as cannabis; often rolled into a joint or blunt. This combination is known as "primo", "hype", "shake and bake",a "turbo" a "yolabowla" "SnowCaps", "B-151er", a "cocoapuff", a "dirty" a "woo", or "geeking." Crack smokers who are being drug tested may also make their "primo" with cigarette tobacco instead of cannabis, since a crack smoker can test clean within two to three days of use, if only urine (and not hair) is being tested.

Powder cocaine is sometimes smoked, but it is inefficient as the heat involved destroys much of the chemical. One way of smoking powder is to put a "bump" into the end of an unlit cigarette, smoking it in one go as the user lights the cigarette normally.

Oral

Cocaine can aid as an oral anesthetic. Many users rub the powder along the gum line, which renders the gums and teeth numb: hence the colloquial names of "numbies," or "gummy," for this type of administration. This is commonly done with the small amounts of cocaine remaining on a surface after insufflation. Another oral method is to wrap up some cocaine in rolling paper and swallow it. This is called "parachuting".

Mechanism of action

The pharmacodynamics of cocaine are complex. One significant effect of cocaine on the central nervous system is the blockage of the dopamine transporter protein (DAT), hence cocaine is called a dopamine reuptake inhibitor. Brain regions that are rich with dopaminergic neurons are the ventral tegmental area (VTA), and the substantia nigra (SN). The dopamine (DA) neurons of the VTA send axons to the nucleus accumbens (nAC)and the prefrontal cortex (PFC) and release DA presynaptically on the neurons in these regions. While the precise role of DA in the subjective experience of reward is controversial among neuroscientists, the release of DA in the nAC is widely considered to be responsible for cocaine's rewarding effects. This conclusion is largely based on laboratory data involving rats that are trained to self-administer cocaine intravenously (i.v.). If DA antagonists are infused directly into the nAC, well-trained rats self-administering cocaine will undergo extinction (i.e., initially increase responding only to stop completely) thereby indicating that cocaine is no longer reinforcing (i.e., rewarding) drug-seeking behavior.

A monoamine transmitter by a neuron for signal firing is normally recycled via the transporter to terminate the signal and to spare transmitter resources. The transporter binds the transmitter and pumps it out of the synaptic cleft back into the pre-synaptic neuron. There it is taken up into storage vesicles. Cocaine binds tightly at the DAT forming a

complex that blocks the transporter's function, this also blocks the reuptake of the transmitter. Once released into the extracellular space (synaptic cleft) dopamine accumulates there, because the recycling mechanism is inhibited by the cocaine. This results in an enhanced and prolonged post-synaptic effect of dopaminergic signalling at dopamine receptors on the receiving neuron. Prolonged exposure to cocaine, as occurs with habitual use, leads to homeostatic dysregulation of normal (i.e., without cocaine) dopaminergic signaling via downregulation of D1 receptors and enhanced signal transduction. The decreased dopaminergic signalling after chronic cocaine use may contribute to depressive mood disorders and sensitize this important brain reward circuit to the reinforcing effects of cocaine (e.g., enhanced dopaminergic signalling only when cocaine is self-administered). This sensitization contributes to the intractable nature of addiction and relapse.

Cocaine is also a less potent blocker of the norepinephrine transporter (NET) and serotonin transporter (SERT). Cocaine also blocks sodium channels, thereby interfering with the propagation of action potentials; thus, like lignocaine and novocaine, it acts as a local anesthetic. Cocaine also causes vasoconstriction, thus reducing bleeding during minor surgical procedures. The locomotor enhancing properties of cocaine may be attributable to its enhancement of dopaminergic transmission from the substantia nigra. Recent research points to an important role of circadian mechanisms[18] and clock genes[19] in behavioral actions of cocaine.

Because nicotine increases the levels of dopamine in the brain, many cocaine users find that consumption of tobacco products during cocaine use enhances the euphoria. This, however, may have undesirable consequences, such as uncontrollable chain smoking during cocaine use (even users who don't normally smoke cigarettes have been known to chain smoke when using cocaine), in addition to the detrimental health effects and the additional strain on the cardiovascular system caused by tobacco.

Metabolism and excretion

Cocaine is extensively metabolized, primarily in the liver, with only about 1% excreted unchanged in the urine. The metabolism is dominated by hydrolytic ester cleavage, so the eliminated metabolites consist mostly of benzoylecgonine, the major metabolite, and in lesser amounts ecgonine methyl ester and ecgonine.

If taken with alcohol, cocaine combines with the ethanol in the liver to form cocaethylene, which is both more euphorigenic and has higher cardiovascular toxicity than cocaine by itself.

Cocaine metabolites are detectable in urine for up to four days after cocaine is used. Benzoylecgonine can be detected in urine within four hours after cocaine inhalation and remains detectable in concentrations greater than 1000 ng/ml for as long as 48 hours. Detection in hair is possible in regular users until the sections of hair grown during use are cut or fall out.

Effects and health issues

Acute

Cocaine is a potent central nervous system stimulant. Its effects can last from 20 minutes to several hours, depending upon the dosage of cocaine taken, purity, and method of administration.

The initial signs of stimulation are hyperactivity, restlessness, increased blood pressure, increased heart rate and euphoria. The euphoria is sometimes followed by feelings of discomfort and depression and a craving to experience the drug again. Sexual interest and pleasure can be amplified. Side effects can include twitching, paranoia, and impotence, which usually increases with frequent usage.

With excessive dosage the drug can produce hallucinations, paranoid delusions, tachycardia, itching, and formication.

Overdose causes tachyarrhythmias and a marked elevation of blood pressure. These can be life-threatening, especially if the user has existing cardiac problems.

The LD50 of cocaine when administered to mice is 95.1 mg/kg.[20] Toxicity results in seizures, followed by respiratory and circulatory depression of medullar origin. This may lead to death from respiratory failure, stroke, cerebral hemorrhage, or heart-failure. Cocaine is also highly pyrogenic, because the stimulation and increased muscular activity cause greater heat production. Heat loss is inhibited by the intense vasoconstriction. Cocaine-induced hyperthermia may cause muscle cell destruction and myoglobinuria resulting in renal failure. There is no specific antidote for cocaine overdose.

Cocaine's primary acute effect on brain chemistry is to raise the amount of dopamine and serotonin in the nucleus accumbens (the pleasure center in the brain); this effect ceases, due to metabolism of cocaine to inactive compounds and particularly due to the depletion of the transmitter resources (tachyphylaxis). This can be experienced acutely as feelings of depression, as a "crash" after the initial high. Further mechanisms occur in chronic cocaine use.

Chronic

With chronic cocaine intake, brain cells functionally adapt (respond) to strong imbalances of transmitter levels in order to compensate extremes. So receptors disappear from or reappear on the cell surface, resulting more or less in an "off" or "working mode" respectively, or they change their susceptibility for binding partners (ligands) – mechanisms called down-/upregulation. Chronic cocaine use leads to a DAT upregulation, further contributing to depressed mood states. Finally, a loss of vesicular monoamine transporters, neurofilament proteins, and other morphological changes appear to indicate a long term damage of dopamine neurons.

All these effects contribute to the rise in an abuser's tolerance thus requiring a larger dosage to achieve the same effect. The lack of normal amounts of serotonin and dopamine in the brain is the cause of the dysphoria and depression felt after the initial high. The

diagnostic criteria for cocaine withdrawal is characterized by a dysphoric mood, fatigue, unpleasant dreams, insomnia or hypersomnia, E.D., increased appetite, psychomotor retardation or agitation, and anxiety.

Cocaine abuse also has multiple physical health consequences. It is associated with a lifetime risk of heart attack that is seven times that of non-users. During the hour after cocaine is used, heart attack risk rises 24-fold.

Side effects from chronic smoking of cocaine include chest pain, lung trauma, shortness of breath, sore throat, hoarse voice, dyspnea, and an aching, flu-like syndrome. A common misconception is that the smoking of cocaine chemically breaks down tooth enamel and causes tooth decay. However, cocaine does often cause involuntary tooth grinding, known as bruxism, which can deteriorate tooth enamel and lead to gingivitis.

Chronic intranasal usage can degrade the cartilage separating the nostrils (the septum nasi), leading eventually to its complete disappearance. Due to the absorption of the cocaine from cocaine hydrochloride, the remaining hydrochloride forms a dilute hydrochloric acid.[1]

Cocaine may also greatly increase this risk of developing rare autoimmune or connective tissue diseases such as lupus, Goodpasture's disease, vasculitis, glomerulonephritis, Stevens-Johnson syndrome and other diseases.[21][22][23][24] It can also cause a wide array of kidney diseases and renal failure.[25][26] While these conditions are normally found in chronic use they can also be caused by short term exposure in susceptible individuals.

There have been published studies reporting that cocaine causes changes in the frontal lobe of the brain. The full extent of possible brain deterioration from cocaine use is not known.

Cocaine as a local anesthetic

Cocaine was historically useful as a topical anesthetic in eye and nasal surgery, although it is now predominantly used for nasal and lacrimal duct surgery. The major disadvantages of this use are cocaine's intense vasoconstrictor activity and potential for cardiovascular toxicity. Cocaine has since been largely replaced in Western medicine by synthetic local anaesthetics such as benzocaine, proparacaine, and tetracaine though it remains available for use if specified. If vasoconstriction is desired for a procedure (as it reduces bleeding), the anesthetic is combined with a vasoconstrictor such as phenylephrine or epinephrine. In Australia it is currently prescribed for use as a local anesthetic for conditions such as mouth and lung ulcers. Some Australian ENT specialists occasionally use cocaine within the practice when performing procedures such as nasal cauterization. In this scenario dissolved cocaine is soaked into a ball of cotton wool, which is placed in the nostril for the 10-15 minutes immediately prior to the procedure, thus performing the dual role of both numbing the area to be cauterized and also vasoconstriction.

Cocaine trade

Because of the extensive processing it undergoes during preparation, cocaine is generally treated as a 'hard drug', with severe penalties for possession and trafficking. Demand

remains high, and consequently black market cocaine is quite expensive. Unprocessed cocaine, such as coca leaves, is occasionally bought and sold, but this is exceedingly rare as it is much easier and more profitable to conceal and smuggle it in powdered form.

Production

As of 1999, Colombia was the world's leading producer of cocaine. Three-quarters of the world's annual yield of cocaine was produced there, both from cocaine base imported from Peru (primarily the Huallaga Valley) and Bolivia, and from locally grown coca. There was a 28 percent increase from the amount of potentially harvestable coca plants which were grown in Colombia in 1998. This, combined with crop reductions in Bolivia and Peru, made Colombia the nation with the largest area of coca under cultivation. Coca grown for traditional purposes by indigenous communities, a use which is still present and is permitted by Colombian laws, only makes up a small fragment of total coca production, most of which is used for the illegal drug trade. Attempts to eradicate coca fields through the use of defoliants have devastated part of the farming economy in some coca growing regions of Colombia, and strains appear to have been developed that are more resistant or immune to their use. Whether these strains are natural mutations or the product of human tampering is unclear. These strains have also shown to be more potent than those previously grown, increasing profits for the drug cartels responsible for the exporting of cocaine. The cultivation of coca has become an attractive, and in some cases even necessary, economic decision on the part of many growers due to the combination of several factors, including the persistence of worldwide demand, the lack of other employment alternatives, the lower profitability of alternative crops in official crop substitution programs, the eradication-related damages to non-drug farms, and the spread of new strains of the coca plant.

Estimated Andean Region Coca Cultivation and Potential Pure Cocaine Production, 2000–2004.[27]\

	2000	2001	2002	2003	2004
Net Cultivation (km²)	1875	2218	2007.5	1663	1662
Potential Pure Cocaine Production (tonnes)	770	925	830	680	645

Trafficking and distribution

Organized criminal gangs operating on a large scale dominate the cocaine trade. Most cocaine is grown and processed in South America, particularly in Colombia and Peru, and smuggled into the United States and Europe, where it is sold at huge markups.

Cocaine shipments from South America transported through Mexico or Central America are generally moved over land or by air to staging sites in northern Mexico. The cocaine is then broken down into smaller loads for smuggling across the U.S.–Mexico border. The primary cocaine importation points in the United States are in Arizona, southern California,

southern Florida, and Texas. Typically, land vehicles are driven across the U.S.-Mexico border.

Cocaine is also carried in small, concealed, kilogram quantities across the border by couriers known as “mules” (or “burros”), who cross a border either legally, e.g. through a port or airport, or illegally through undesignated points along the border. The drugs may be strapped to the waist or legs or hidden in bags, or hidden in the body. If the mule gets through without being caught, the gangs will reap most of the profits. If he or she is caught however, gangs will sever all links and the mule will usually stand trial for trafficking by him- or herself.

Cocaine traffickers from Colombia, and recently Mexico, have also established a labyrinth of smuggling routes throughout the Caribbean, the Bahama Island chain, and South Florida. They often hire traffickers from Mexico or the Dominican Republic to transport the drug. The traffickers use a variety of smuggling techniques to transfer their drug to U.S. markets. These include airdrops of 500–700 kg in the Bahama Islands or off the coast of Puerto Rico, mid-ocean boat-to-boat transfers of 500–2,000 kg, and the commercial shipment of tonnes of cocaine through the port of Miami.

Bulk cargo ships are also used to smuggle cocaine to staging sites in the western Caribbean–Gulf of Mexico area. These vessels are typically 150–250 foot (50–80 m) coastal freighters that carry an average cocaine load of approximately 2.5 tonnes. Commercial fishing vessels are also used for smuggling operations. In areas with a high volume of recreational traffic, smugglers use the same types of vessels, such as go-fast boats, as those used by the local populations.

"Black cocaine"

Traffickers have also started using a method whereby a substance such as iron thiocyanate,[1] a mixture of cobalt and ferric chloride,[28] or a mixture of charcoal and iron filings [29] is added to cocaine hydrochloride to produce “black cocaine.” The cocaine in this substance is not detected by standard chemical tests such as the Becton Dickinson test kit. The substance was first identified after a seizure in March 1998 in Germany, which was then tracked back to discover 250 lb of black cocaine ready for transport at Bogotá’s airport. [29]

Addiction

Cocaine addiction is the excessive intake of cocaine, and can result in physiological damage, lethargy, depression, or a potentially fatal overdose. The immediate craving to use more cocaine is strong and very common, because euphoric effects usually subside in most users within an hour of the last dosage, leading to serial cocaine readministrations, and prolonged, multi-dose binge use in those who are addicted. When administration stops after binge use, it is followed by a "crash", the onset of severely dysphoric mood with escalating exhaustion until sleep is achieved. Resumption of use may occur upon awakening or may not occur for several days, but the intense euphoria such use can, as it has in many users, produce intense craving and develop rather quickly into addiction. The risk[30] of becoming cocaine-dependent within 2 years of first use(recent-onset) is 5-6%; after 10 years, it's 15-16%.

These are the aggregate rates for all types of use considered, i.e., smoking, snorting, injecting. Among recent-onset users, the relative rates are higher for smoking (3.4 times) and much higher for injecting (31 times). They also vary, based on other characteristics, such as gender: among recent-onset users, females are 3.3 times more likely to become addicted, compared to males; age: among recent-onset users, those who started using at ages 12 or 13 were 4 times as likely to become addicted, compared to those who started between ages 18 and 20; and race: among recent-onset users, non-Hispanic Blacks are 7 times as likely to become addicted, compared to non-Hispanic Whites. Many habitual abusers develop a transient manic-like condition similar to amphetamine psychosis and schizophrenia, whose symptoms include aggression, severe paranoia, and tactile hallucinations (including the feeling of insects under the skin, or "coke bugs") during binges.[31]

Cocaine has positive reinforcement effects, which refers to the effect that certain stimuli have on behavior. Good feelings become associated with the drug, causing a frequent user to take the drug as a response to bad news or mild depression. This activation strengthens the response that was just made. If the drug was taken by a fast acting route such as injection or inhalation, the response will be the act of taking more cocaine, so the response will be reinforced. Powder cocaine, being a club drug is mostly consumed in the evening and night hours. Because cocaine is a stimulant, a user will often drink large amounts of alcohol during and after usage or smoke cannabis to dull "crash" effects and hasten slumber. Benzodiazepines (e.g., xanax, rohypnol) are also used for this purpose. Other drugs such as heroin and various pharmaceuticals are often used to amplify reinforcement or to minimize such negative effects, further increasing addiction potential and harmfulness.

It has been shown in studies that rhesus monkeys provided with a mechanism of cocaine self-administration prefer the drug over food that is in the cage. This happens even when the monkeys are starving.[32]

It is speculated that cocaine's addictive properties stem partially from its DAT-blocking effects (in particular, increasing the dopaminergic transmission from ventral tegmental area neurons). However, a study has shown that mice with no dopamine transporters still exhibit the rewarding effects of cocaine administration.[33] Later work demonstrated that a combined DAT/SERT knockout eliminated the rewarding effects.[34] The rewarding effects of cocaine are influenced by circadian rhythms,[35] possibly by involving a set of genes termed "clock genes".[36] However, chronic cocaine addiction is not solely due to cocaine reward. Chronic repeated use is needed to produce cocaine-induced changes in brain reward centers and consequent chronic dysphoria (described above under "Effects and Health Issues - Chronic"). Dysphoria magnifies craving for cocaine because cocaine reward rapidly, albeit transiently, improves mood. This contributes to continued use and a self-perpetuating, worsening condition, since those addicted usually cannot appreciate that long-term effects are opposite those occurring immediately after use.

Treatment

Cognitive Behavioral Therapy (CBT) shows promising results. One or more cocaine vaccines exist or are on trial that will stop desirable effects from the drug. The National Institutes of Health of an unspecified country is researching modafinil, a narcolepsy drug and

mild stimulant, as a potential cocaine treatment. Twelve-step programs such as Cocaine Anonymous (modeled on Alcoholics Anonymous) are claimed by many cocaine addicts to be helpful in achieving long-term abstinence. These spiritual programs have no statistically-measurable effect as Alcoholics Anonymous does not release any quantifiable measure of its success rates. There are, however, many recovering addicts who claim this program has aided them.

GVG

Studies have shown that gamma vinyl-gamma-aminobutyric acid (gamma vinyl-GABA, or GVG), a drug normally used to treat epilepsy, blocks cocaine's action in the brains of primates. GVG increases the amount of the neurotransmitter GABA in the brain and reduces the level of dopamine in the region of the brain that is thought to be involved in addiction. In January 2005 the U.S. Food and Drug Administration gave permission for a Phase I clinical trial of GVG for the treatment of addiction. Another drug currently tested for anti-addictive properties is the cannabinoid antagonist rimonabant.

GBR 12909

GBR 12909 (Vanoxerine) is a selective dopamine uptake inhibitor. Because of this, it reduces cocaine's effect on the brain, and may help to treat cocaine addiction. Studies have shown that GBR, when given to primates, suppresses cocaine self-administration.

Venlafaxine

Venlafaxine (Effexor), although not a dopamine re-uptake inhibitor, is a serotonin-norepinephrine reuptake inhibitor that has been successfully used to combat the depression caused by cocaine withdrawal and to a lesser extent, the addiction associated with the drug itself. Venlafaxine has been shown to have significant withdrawal problems itself, and can lead to lifetime use due to these withdrawal effects. A statisically significant number of people prescribed Effexor have committed suicide (2 attempts per 1000 patients, vs 1.56 suicides per 1,000 untreated depressives).

Coca teas

Coca herbal tea has been used for the treatment of cocaine dependence. The effects of the coca tea are a nice stimulation and mood lift. It doesn't produce any significant numbing of the mouth nor does it give a rush like snorting cocaine. Much of the effect of coca seems to come from the secondary alkaloids, as it is not only quantitatively different from pure cocaine but also qualitatively different. In one study, coca tea was used—in addition to counseling—to treat 23 addicted coca-paste smokers in Lima, Peru. Relapses fell from an

average of 4.35 times per month before treatment with coca tea to 1.22 during the treatment. Abstinence length increased from an average of 32 days prior to treatment to 217.2 days during treatment. These results suggest that coca tea is an effective method for preventing relapse during treatment for cocaine addiction.[37]

Legal status

The production, the distribution and the sale of cocaine products is restricted (and illegal in most contexts) in most countries. Since 1914, when The Harrison Narcotics Tax Act passed in the U.S., cocaine has been considered a 'hard drug.' In Colombia, the indigenous population is allowed to grow coca for traditional reasons. All other coca is considered part of the illegal black market. In parts of Africa, it is a crime to be in possession of cocaine or even be seen with it. In South America, cultivation of coca is allowed only with special permission; however, it is a crime to posses processed cocaine. Some parts of Europe and Australia allow processed cocaine for medicinal uses only. Also, in some parts of the Middle East and Asia, being in possession of cocaine can be punishable by death.

Usage

In the United States

Overall usage

In the late 1800's, many authors of this time, including Freud, openly admitted to going on cocaine binges to complete their works. But at the turn of the twentieth century, the dangers of cocaine were becoming apparent and the public did not want a society of drug addicts. There was a public outcry against the use and abuse of cocaine. Groups were demonizing cocaine users as the low-lifes of society. There was also a racial backlash, and many people blamed the African American community.

During the 60's cocaine had become mainstream again, yet it was still illegal. Prices of cocaine began to rise, and those of the lower class could no longer afford their addiction. Cocaine has become the second most popular illegal recreational drug in the U.S.Cocaine is generally used by privileged middle to upper class communities. It is also popular amongst college students, not just to aide in studying, but also as a party drug. Its users span over different ages, races, and professions. In the 1970's and 80's the drug became particularly popular in the disco culture as cocaine usage was very common and popular in many discos such as Studio 54.

The National Household Survey on Drug Abuse (NHSDA) reported in 1999 that cocaine was used by 3.7 million Americans, or 1.7 percent of the household population age 12 and older. Estimates of the current number of those who use cocaine regularly (at least once per month) vary, but 1.5 million is a widely accepted figure within the research community.

Although cocaine use had not significantly changed over the six years prior to 1999, the number of first-time users went up from 574,000 in 1991, to 934,000 in 1998 — an increase of 63%. While these numbers indicated that cocaine is still widely present in the United

States, cocaine use was significantly less prevalent than it was during the early 1980s. Cocaine use peaked in 1982 when 10.4 million Americans (5.6 percent of the population) reportedly used the drug.

Usage among youth

The 1999 Monitoring the Future (MTF) survey found the proportion of American students reporting use of powder cocaine rose during the 1990s. In 1991, 2.3 percent of eighth-graders stated that they had used cocaine in their lifetime. This figure rose to 4.7 percent in 1999. For the older grades, increases began in 1992 and continued through the beginning of 1999. Between those years, lifetime use of cocaine went from 3.3 percent to 7.7 percent for tenth-graders and from 6.1 percent to 9.8 percent for twelfth-graders. Lifetime use of crack cocaine, according to MTF, also increased among eighth-, tenth-, and twelfth-graders, from an average of 2 percent in 1991 to 3.9 percent in 1999.

Perceived risk and disapproval of cocaine and crack use both decreased during the 1990s at all three grade levels. The 1999 NHSDA found the highest rate of monthly cocaine use was for those aged 18–25 at 1.7 percent, an increase from 1.2 percent in 1997. Rates declined between 1996 and 1998 for ages 26–34, while rates slightly increased for the 12–17 and 35+ age groups. Studies also show people are experimenting with cocaine at younger ages. NHSDA found a steady decline in the mean age of first use from 23.6 years in 1992 to 20.6 years in 1998.

Availability

Cocaine is readily available in all major countries' metropolitan areas. According to the Summer 1998 Pulse Check, published by the U.S. Office of National Drug Control Policy, cocaine use had stabilized across the country, with a few increases reported in San Diego, Bridgeport, Miami, and Boston. In the West, cocaine usage was lower, which was thought to be because some users were switching to methamphetamine, which was cheaper and provides a longer-lasting high. Numbers of cocaine users are still very large, with a concentration among city-dwelling youth.

Cocaine is typically sold to users by the gram ($40-$80US) or eight ball (3.5 grams, or roughly 1/8th oz; hence the term "eight ball") ($100-$250). Quality and price can vary dramatically depending on demand and supply.

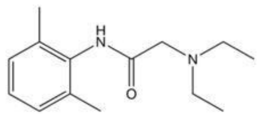
Lidocaine



Systematic (IUPAC) name

2-(diethylamino)-
N-(2,6-dimethylphenyl)acetamide

Identifiers

CAS number 137-58-6

ATC code N01**BB02** C01**BB01**

PubChem 3676

DrugBank APRD00479

Chemical data

Formula $C_{14}H_{22}N_2O$

Mol. weight 234.34 g/mol

Physical data

Melt. point 68 °C (154 °F)

Pharmacokinetic data

Bioavailability 35% (oral), 3% (topical)

Metabolism hepatic 90% (CYP1A2)

Half life 1.5–2 hours

Excretion renal

Therapeutic considerations

Pregnancy cat. A (Australia)

Legal status Schedule 4 (Australia)

Routes IV, subcutaneous, topical

Lidocaine (INN) (IPA: [Èlajdokejn]) or *lignocaine* (former BAN) (IPA: [Èljgnokejn]) is a common local anesthetic and antiarrhythmic drug. The most commonly encountered lidocaine preparations are marketed by AstraZeneca under the brand names *Xylocaine* and *Xylocard*, though lidocaine is also found in many other proprietary preparations.

History

Lidocaine, the first amino amide-type local anesthetic, was developed by Nils Löfgren and Bengt Lundqvist in 1943 and first marketed in 1948.

Pharmacokinetics

Lidocaine has a more rapid onset of action and longer duration of action than amino ester-type local anesthetics such as procaine. It is approximately 90% metabolized in the liver by CYP1A2 (and to a minor extent CYP3A4) to the pharmacologically-active metabolites monoethylglycinexylidide and glycinexylidide.

The elimination half-life of lidocaine is approximately 1.5–2 hours in most patients. This may be prolonged in patients with hepatic impairment (average 343 minutes) or congestive heart failure (average 136 minutes). (Thomson et al., 1973)

Pharmacology

Anesthesia

Lidocaine alters depolarization in neurons, by blocking the fast sodium (Na^+) channels in the cell membrane. With sufficient blockade, the membrane will not depolarise and so not transmit an action potential, leading to its anesthetic effects.

Antiarrhythmia

Lidocaine is classified as a Class Ib antiarrhythmic agent, blocking the sodium channel of the cardiac action potential, which decreases automaticity by reducing the slope of phase 0 of depolarization with little effect on the PR interval, QRS complex or QT interval.

Clinical use

Indications

Indications for the use of lidocaine include:

- Topical, infiltration, nerve block, ophthalmic, epidural and intrathecal anaesthesia, IV regional anaesthesia (IVRA)
- Treatment of serious ventricular arrhythmias (IV preparations), including VF (Ventricular Fibrillation) associated with cardiac arrest

- Neuropathic pain, including postherpetic neuralgia

Contraindications

Contraindications for the use of lidocaine include:

- Heart block, second or third degree (without pacemaker) Severe sinoatrial block (without pacemaker) Serious adverse drug reaction to lignocaine or amide local anaesthetics Concurrent treatment with quinidine, flecainide, disopyramide, procainamide (Class I antiarrhythmic agents)

Adverse drug reactions

Adverse drug reactions (ADRs) are rare when lidocaine is used as a local anesthetic and is administered correctly. Most ADRs associated with lidocaine for anesthesia relate to administration technique (resulting in systemic exposure) or pharmacological effects of anesthesia, however allergic reactions can rarely occur.

Systemic exposure to excessive quantities of lidocaine mainly result in central nervous system (CNS) and cardiovascular effects – CNS effects usually occur at lower plasma concentrations and additional cardiovascular effects present at higher concentrations, though cardiovascular collapse may also occur with low concentrations. CNS effects may include CNS excitation (nervousness, tingling around the mouth, tinnitus, tremor, dizziness, blurred vision, seizures) followed by depression (drowsiness, loss of consciousness, respiratory depression and apnea). Cardiovascular effects include hypotension, bradycardia, arrhythmias, and/or cardiac arrest – some of which may be due to hypoxemia secondary to respiratory depression. (Rossi, 2006)

ADRs associated with the use of intravenous lidocaine are similar to toxic effects from systemic exposure above. These are dose-related and more frequent at high infusion rates (e3 mg/minute). Common ADRs include: headache, dizziness, drowsiness, confusion, visual disturbances, tinnitus, tremor, and/or paraesthesia. Infrequent ADRs assocaited with the use of lidocaine include: hypotension, bradycardia, arrhythmias, cardiac arrest, muscle twitching, seizures, coma, and/or respiratory depression. (Rossi, 2006)

Dosage forms

Lidocaine, usually in the form of *lidocaine hydrochloride*, is available in various forms including:

- Injected local anesthetic (sometimes combined with
- Dermal patch (sometimes combined with prilocaine)
- Intravenous injection (sometimes combined with
- Intravenous infusion
- Nasal instillation/spray (combined with phenylephrine)
- Oral gel (often referred to as "viscous lidocaine" or abbreviated "lidocaine visc" or "lidocaine hcl visc" in pharmacology)

- Oral liquid
- Topical gel (as with Aloe Vera gels that include Lidocaine)
- Topical liquid

Carbon tetrachloride

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Chloroform, also known as *trichloromethane* and *methyl trichloride*, is a chemical compound with formula $CHCl_3$. It does not support combustion in air, although it will burn when mixed with more flammable substances. It is a member of a subset of environmental pollutants known as *trihalomethanes*, a by-product of chlorination of drinking water and a long-standing health concern.

History

Chloroform was discovered in July, 1831 by American physician Samuel Guthrie (1782-1848), and independently a few months later by French chemist Eugène Soubeiran (1797-1859) and Justus von Liebig (1803-1873) in Germany. Soubeiran produced chloroform through the action of chlorine bleach powder (calcium hypochlorite) upon acetone (propanone) or ethanol (an application of the generic process known as the haloform reaction). Chloroform was named and chemically characterised in 1834 by Jean-Baptiste Dumas (1800-1884). Its anaesthetic properties were noted early in 1847 by Marie-Jean-Pierre Flourens (1794-1867) and Robert James Fegle (1790-1842).

In 1847, the Edinburgh obstetrician James Young Simpson first used chloroform for general anesthesia during childbirth. The use of chloroform during surgery expanded rapidly thereafter in Europe. In the United States, chloroform began to replace ether as an anesthetic at the beginning of the 20th century; however, it was quickly abandoned in favor of ether upon discovery of its toxicity, especially its tendency to cause fatal cardiac arrhythmia analogous to what is now termed "sudden sniffer's death". Ether is still the preferred anesthetic in some developing nations due to its high therapeutic index and low price. Trichloroethylene, a halogenated aliphatic hydrocarbon related to chloroform, was proposed as a safer alternative, though it, too, was later found to be carcinogenic.

Production

Industrially, chloroform is produced by heating a mixture of chlorine and either chloromethane or methane to 400-500°C. At this temperature, a free radical halogenation occurs, converting the methane or chloromethane to progressively more chlorinated compounds.

$CH_4 + Cl_2$ ’ $CH_3Cl + HCl$ $CH_3Cl + Cl_2$ ’ $CH_2Cl_2 + HCl$ $CH_2Cl_2 + Cl_2$ ’ $CHCl_3 + HCl$ $CHCl_3 + Cl_2$ ’ $CCl_4 + HCl$

The output of this process is a mixture of the four chloromethanes, chloromethane, dichloromethane, chloroform (trichloromethane), and carbon tetrachloride, which are then separated by distillation.

The first industrial process was the reaction of acetone (or ethanol) with sodium hypochlorite or calcium hypochlorite. The chloroform can be removed from the resulting sodium acetate or calcium acetate (or sodium formate or calcium formate if ethanol is the starting material) by distillation. The reaction mechanism is called haloform reaction, and is still used for the production of bromoform and iodoform.

This reaction can also occur inadvertently when cleaning around the house. Sodium hypochlorite solution (bleach) and acetone (nail-varnish remover) produces chloroform, sodium hydroxide, sodium acetate, and sodium chloride. There have been reported cases of this method being used in the UK to synthesise chloroform in the home.

Deuterated chloroform is prepared by the reaction of sodium deuteroxide with chloral hydrate. Some of the aldehyde hydrogen is retained in the product, though, and samples of higher isotopic purity are obtained from trichloroacetophenone as starting material.

Uses

In the late 19th and early 20th centuries, chloroform was used as an inhaled anesthetic during surgery. However, safer, more flexible drugs have entirely replaced it in this role. The major use of chloroform today is in the production of the freon refrigerant R-22. However, as the Montreal Protocol takes effect, this use can be expected to decline as R-22 is replaced by refrigerants that are less liable to result in ozone depletion.

Smaller amounts of chloroform are used as a solvent in the pharmaceutical industry and for producing dyes and pesticides. It is used as a solvent for research in academic chemistry laboratories, also. As a solvent it can be used to bond pieces of acrylic glass (which is also known under the trade name 'Perspex'). Chloroform is one of the most effective known solvents for alkaloids in base form, and may be used to extract nitrogenous chemicals from plant material for pharmaceutical processing. It is commercially used to extract morphine from poppies, scopolamine from Datura plants, and so on.

Chloroform reacts with aqueous sodium hydroxide (preferably in the presence of a phase transfer catalyst) to produce dichlorocarbene. This is used to effect ortho-formylation of activated aromatic rings such as phenols, producing aryl aldehydes in a reaction known as the Reimer-Tiemann reaction. Alternatively the carbene may be trapped by an alkene to form a cyclopropane derivative.

Chloroform containing deuterium (heavy hydrogen), $CDCl3$, is the most common solvent used in NMR spectroscopy.

Safety

As might be expected from its use as an anesthetic, inhaling chloroform vapors depresses the central nervous system. Breathing about 900 parts of chloroform per million parts air (900 parts per million) for a short time can cause dizziness, fatigue, and headache. Chronic chloroform exposure may cause damage to the liver (where chloroform is metabolized to phosgene) and to the kidneys, and some people develop sores when the skin is immersed in

chloroform. Approximately 10% of the population has an allergic reaction to chloroform that produces a fever of around 40°C (104°F) upon exposure.

Animal studies have shown that miscarriages occur in rats and mice that have breathed air containing 30 to 300 ppm chloroform during pregnancy and also in rats that have ingested chloroform during pregnancy. Offspring of rats and mice that breathed chloroform during pregnancy have a higher incidence of birth defects, and abnormal sperm have been found in male mice that have breathed air containing 400 ppm chloroform for a few days. The effect of chloroform on reproduction in humans is unknown.

Chloroform once appeared in toothpastes, cough syrups, ointments, and other pharmaceuticals, but it has been banned in consumer products in the United States since 1976.

The NTP's eleventh report on carcinogens implicates it as reasonably anticipated to be a human carcinogen, a designation equivalent to IARC class 2A. It has been most readily associated with hepatocellular carcinoma. Caution is mandated during its handling in order to minimize unnecessary exposure; safer alternatives, such as dichloromethane, have resulted in a substantial reduction of its use as a solvent.

During prolonged storage hazardous amounts of phosgene can accumulate in the presence of oxygen and ultraviolet light. To prevent accidents commercial material is stabilized with ethanol or amylene, but samples that have been recovered or dried no longer contain any stabilizer and caution must be taken with those. Suspicious bottles should be tested for phosgene. Filter paper strips, wetted with 5% diphenylamine, 5% dimethylaminobenzaldehyde, and then dried, turn yellow in phosgene vapor.

Due to its volatile nature, laboratory work with chloroform should be performed under a fume hood to avoid inhaling its fumes. Another problem with its volatility is that it can be difficult to pipette.

Diethyl ether

Related Ethers dimethyl ether

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Diethyl ether, also known as *ether* and *ethoxyethane*, is a clear, colorless, and highly flammable liquid with a low boiling point and a characteristic smell. Diethyl ether has the formula CH_3-CH_2-O-CH_2-CH_3. It is used as a common solvent and has been used as a general anesthetic. Diethyl ether has a high cetane number of 85 - 96 and is used as a starting fluid for diesel and gasoline engines. Ether is sparingly soluble in water (7 g/100 ml).

History

Alchemist Raymundus Lullus is credited with discovering the compound in 1275, although there is no contemporary evidence of this. It was first synthesized in 1540 by

Valerius Cordus, who called it "*oil of sweet vitriol*" (*oleum dulci vitrioli*)—the name was due to the fact that it was originally discovered by distilling a mixture of ethanol and sulfuric acid (then known as oil of vitriol)—and noted some of its medicinal properties. At about the same time, Theophrastus Bombastus von Hohenheim, better known as Paracelsus, discovered ether's analgesic properties. The name ether was given to the substance in 1730 by A.S.Frobenius.

Anesthetic use

The American doctor Crawford Williamson Long, M.D., was the first surgeon to use it as a general anesthetic, on March 30, 1842. William T.G. Morton is credited with the first public demonstration of ether anesthesia on October 16, 1846 at the Ether Dome in Boston, Massachusetts. The use of flammable ether waned as nonflammable anesthetic agents such as halothane became available.

Because of its high volatility, low ignition point, and tendency to form explosive peroxides, diethyl ether must be used with care in laboratory settings.

Ether may be used to anesthetize ticks before removing them from an animal or a person's body. The anesthesia relaxes the tick and prevents it from maintaining its mouthpart under the skin.

Recreational use

The anesthetic effects of ether have made it a recreational drug, although not a popular one. Diethyl ether is not as toxic as other solvents used as recreational drugs.

Ether, mixed with ethanol, was marketed in the 19th century as a cure-all and recreational drug, during one of Western society's temperance movements. At the time, it was considered improper for women to consume alcoholic beverages at social functions, and sometimes ether-containing drugs would be consumed instead. A cough medicine called Hoffmann's Drops was marketed at the time as one of these drugs, and contained both ether and alcohol in its capsules. [1] Ether tends to be difficult to consume alone, and thus was often mixed with drugs like ethanol for recreational use. Ethyl ether is listed as a Table II precursor under the United Nations Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances[2].

Due to its immiscibility with water and the fact that non-polar organic compounds are highly soluble in it, Ether is also used in the production of freebase cocaine.

Precautions

Diethyl ether is highly flammable. Its vapors are denser than air and will accumulate if proper ventilation is not present. Simple static electricity will ignite ether vapors. Diethyl ether vapors ignite explosively, and should only be used inside a fume hood.

Additionally, diethyl ether is prone to peroxide formation, and can form explosive diethyl ether peroxide. Ether peroxides are higher boiling and are contact explosives when dry. Ether should never be distilled to dryness, as the risk of explosion increases dramatically. Diethyl ether is typically supplied with BHT (2,6-di-tert-butyl-4-methylphenol), which

reduces the formation of peroxides. Bottles older than 3 months should be routinely tested for peroxides. An iron wire, releasing Fe(III) ions catalyzing the peroxide decomposition, was often added to bottles with diethyl ether as a preventive measure, however, Fe(III) ions also strongly enhance peroxide formation. Storage over NaOH precipitates the intermediate ether hydroperoxides.

Ketamine is a general dissociative anaesthetic for human and veterinary use. Its hydrochloride salt is sold as *Ketanest*®, *Ketaset*®, and *Ketalar*®. Pharmacologically it is very similar to other dissociative anesthetics such as tiletamine, memantine and phencyclidine (PCP). As with many other pharmaceuticals, ketamine is used extramedically as a recreational drug.

Ketamine is a chiral compound, with two distinct enantiomers. Most pharmaceutical ketamine preparations are racemic, however reportedly some brands have (mostly undocumented) differences in enantiomeric proportions.

History

Ketamine was first synthesized in 1962 in an attempt to find a safer anaesthetic alternative to Phencyclidine (PCP), which was more likely to cause hallucinations and seizures. The drug was first given to American soldiers during the Vietnam War, but today in the developed world its use on humans has been dramatically curtailed because of exaggerated concern about its potential to cause emergence phenomena including out of body experiences in clinical practice. However, it is still used widely in veterinary medicine, or as a battlefield anesthetic in developing nations.

Ketamine's side effects eventually made it a popular psychedelic in 1965. The drug was used in psychiatric and other academic research through the 1970s, culminating in 1978 with the publishing of John Lilly's The Scientist, a book documenting the author's ketamine, LSD, and isolation tank experiments. The incidence of recreational ketamine use increased through the end of the century, especially in the context of raves and other parties. The increase in illicit use prompted ketamine's placement in Schedule III of the United States Controlled Substance Act in August 1999. In the United Kingdom, it became outlawed and labelled a Class C drug on January 1, 2006.[1] In Canada, as of August 31, 2005, ketamine is classified as a Schedule III narcotic.

Medical use

10 ml bottles of Ketamine *Indicated for:*

Pain relief, surgical anaesthesia
Recreational uses:

Dissociative

psychedelic
Contraindications:

Alcohol

Other **sedatives**

Stimulants

Side effects:

Severe: Impairs all senses, especially:

Sight
Balance
Sense of time
Cardiovascular:
Partial depressant
Gastrointestinal:
Nausea
Musculoskeletal:
Relaxant
Neurological:

Analgesia

Respiratory:
Partial depressant/stimulant

Since it suppresses breathing much less than most other available anaesthetics, ketamine is still used in human medicine as a first-choice anaesthetic for victims with unknown medical history (e.g. from traffic accidents), in podiatry and other minor surgery, and occasionally for the treatment of migraine. There is ongoing research in France, Russia, and the U.S. into the drug's usefulness in pain therapy, depression suppression, and for the treatment of alcoholism and heroin addiction. In veterinary medicine, ketamine is often used for its anaesthetic and analgesic effects on cats, dogs, rabbits, rats, and other small animals. Veterinarians often use ketamine with sedative drugs to produce balanced anaesthesia and analgesia, and as a constant rate infusion to help prevent pain wind-up. Ketamine is used to manage pain among horses and other large animals, though it has less effect on bovines.

Ketamine may be used in small doses (0.1–0.5 mg/kg/h) as an analgesic, particularly for the treatment of pain associated with movement and neuropathic pain. It has the added benefit of counter-acting spinal sensitization or wind-up phenomena experienced with chronic pain. At these doses, the psychotropic side effects are less apparent and well managed with benzodiazepines. Ketamine is a co-analgesic, requiring a concomitant low-dose opioid to be effective.

The effect of Ketamine as a depressant on the respiratory and circulatory systems is less than that of other anaesthetics. When used at anaesthetic doses, it will sometimes stimulate rather than depress the circulatory system. It is sometimes possible to perform ketamine anaesthesia without protective measures to the airways. Ketamine is also a potent analgesic and can be used in sub-anaesthetic doses to relieve acute pain; however, its psychotropic properties must be taken into account. Patients have reported vivid hallucinations, "going into other worlds" or "seeing God" while anaesthetized, and these unwanted psychological side-effects have reduced the use of ketamine in human medicine.

Experimental Antidepressant Use

The National Institute of Health News reports that a study of 17 patients led by Dr Carlos Zarate Jr. of the National Institute of Mental Health found that ketamine significantly improved treatment-resistant major depression within hours of injection. [1] The improvement lasted up to one week after the single dose. [2] The patients in the study were previously treatment resistant, having tried an average of six other treatments that failed. The importance of these findings was articulated by NIMH director Dr Thomas Insel: "To my knowledge, this is the first report of any medication or other treatment that results in such a pronounced, rapid, prolonged response with a single dose. These were very treatment-resistant patients." The researchers apparently attribute the effect to ketamine being an NMDA receptor antagonist. The study appears in the Archives of General Psychiatry. [3] Those findings of Zarate et al corroborate earlier findings by Berman et all. [4]

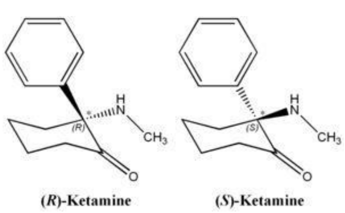
Treatment of addiction

The Russian doctor Evgeny Krupitsky (who is Clinical Director of Research for the Saint Petersburg Regional Center for Research in Addiction and Psychopharmacology) has gained encouraging results by using ketamine as part of a treatment for alcohol addiction which combines psychedelic and aversive techniques [5]. This method involved psychotherapy, controlled ketamine use and group therapy, and resulted in 60 of the 86 alcoholic males selected for the study remaining fully abstinent. He has also treated heroin addicts and reached the conclusion that ketamine reduces the craving for heroin without any adverse reaction [6].

Neuropharmacology

Ketamine, like Phencyclidine, is primarily a non-competitive antagonist of the NMDA receptor, which opens in response to binding of the neurotransmitter glutamate. This NMDA receptor mediates the analgesic (reduction of pain) effects of ketamine at low doses. Evidence for this is reinforced by the fact that naloxone, an opioid antagonist, does not reverse the analgesia. Studies also seem to indicate that ketamine is 'use dependent' meaning it only initiates its blocking action once a glutamate binds to the NMDA receptor.

At high, fully anesthetic level doses, ketamine has also been found to bind to opioid mu receptors and sigma receptors. Thus, loss of consciousness that occurs at high doses may be partially due to binding at the opioid mu and sigma receptors.



Ketamine stereochemistry

Ketamine is racemic, and its R and S stereoisomers have different binding affinities: (S)-Ketamine has about four times greater affinity for the PCP site of the NDMA receptor than

does (R)-Ketamine (in guinea pig brain). The S form also seems to be better at inducing the drowsiness than the R form.[2]

The effects seem to take place mainly in the hippocampal formation and in the prefrontal cortex. This evidence, along with the NMDA receptor's connection with the memory formation process, explains ketamine's profound effects on memory and thought. These effects inhibit the filtering function of the brain and may mirror the sensory overload associated with schizophrenia and near death experiences.

Recreational use

Illicit sale

Ketamine sold illicitly comes from diverted legitimate supplies or theft, primarily veterinary clinics. In the US near its border with Mexico, the drug is most commonly acquired in Mexico, where it can be bought over the counter in veterinary clinics, and smuggled across the border.

In 2003, Operation TKO was a probe conducted by the U.S. Drug Enforcement Agency (DEA). As a result of operation TKO, U.S. and Mexican authorities shut down the Mexico City company, Laboratorios Ttokkyo, which was the biggest producer of ketamine in Mexico. According to the DEA, over 80% of ketamine found in the U.S. is of Mexican origin.[3]

Methods of use

Ketamine is sold in either powdered or liquid form. In powdered form, its appearance is similar to that of pharmaceutical grade cocaine and can be insufflated (snorted, also known as "taking bumps"), injected, or placed in beverages. It is also possible to smoke the drug in a joint or pipe, usually mixed with marijuana and tobacco. The smoke has a distinctive bitter taste but the effects of the high hit much faster than when insufflated or ingested. Oral use usually requires more material, but results in a longer trip. The liquid can be heated to drive off the solvent (usually saline), leaving powder. In therapeutic and psychedelic use, the liquid is typically injected intramuscularly. Intravenous injection is uncommon (recreationally), though possible. It is essentially identical in effect to intramuscular injection, but leads to a much quicker onset — usually within 10 to 15 seconds of dosing. Additionally, intravenous injection tends to lead to a more sudden and marked respiratory depression, especially if the solution is injected at too high of a potency (too fast). These factors make intravenous self-injection dangerous.

Some drug users' first contact with ketamine is accidental, from a pill sold as something else (commonly ecstasy). Ketamine is also commonly combined with other drugs to enhance their effects. There have been claims that ketamine has been used as a date rape drug because of its powerful dissociative effects.

Psychological effects

Unlike true psychedelics, ketamine is powerfully reinforcing to many users and compulsive use is frequently reported. Both ketamine pioneer John Lilly and pseudonymous author D.M. Turner reported prolonged periods of 'ketamine dependency', and the latter drowned in a bathtub while on ketamine.

Ketamine produces effects similar to PCP and DXM. Like other dissociative anesthetics in low- to upper-middle dosages, its hallucinogenic effects are only seen against a background lacking sensory stimulation, such as darkness. Some users claim that a trip due to ketamine use is as good or better than that of PCP or LSD because its overt hallucinatory effects are short-acting, lasting an hour or less in most cases. Effects on the senses, judgment, and coordination, however, can last for 18 to 24 hours. Standing up and moving may be more dangerous than lying still in one place.

Like the other dissociative anaesthetics DXM and PCP, hallucinations caused by ketamine are fundamentally different from those caused by tryptamines and phenethylamines. At low doses hallucinations are only seen when one is in a dark room with one's eyes closed, while at medium to high doses the effects are far more intense and obvious. These effects include changes in the perception of distances and durations as well as a slowing of the visual system's ability to update what the user is seeing. There are reports of high-dosage users being able to see their surroundings in two sharp images, as if the brain is unable to merge the images each eye is sending. Speech often sounds unintelligible and auditory hallucinations may occur.

Ketamine puts the user in a dissociated state, meaning that they are less connected to both a sense of self and the reality around them. If a large enough amount is taken, the user may go into or through a "K-hole", a state of wildly dissociated experience in which other worlds or dimensions that are difficult to describe with language are said to be perceived, all the while being completely unaware of one's individual identity or the outside world. A user may feel as though his or her perception is located so deep inside the mind that the real world seems distant (hence the use of a "hole" to describe the experience). Some users may not remember this part of the experience after regaining consciousness, in the same way that a person may forget a dream. The "re-integration" process is slow, and the user gradually becomes aware of surroundings. At first, a user may not remember his or her own name, or even know that they are human, or what that means. Movement is extremely difficult, and a user may not be aware that they have a body at all.

Ketamine in the media

- In the seventh episode of the first season of the American television series The Dead Zone, titled "Enemy Mind," the lead character, psychic Johnny Smith, accidentally inhales Ketamine in aerosol state, and the drug wreaks havoc with his "dead zone," the primary brain center for his psychic visions.
- In the last episode of the second season of the American televison series House, titled "No Reason," the lead character, Dr. Gregory House, is administered Ketamine to try to relieve the terrible leg pain he has been suffering throughout the course of the series. At the beginning of the third season, it seems that the

Ketamine treatment has worked, though by the end of the second episode his pain has returned and he has started using a walking cane and Vicodin again.

- In the sixth episode of the second season of I'm Alan Partridge, entitled "Alan Wide Shut", Alan Partridge attends a radio interview on a program called Prayer Wave to promote his autobiography and has a surreal, barbed conversation with a woman called Kate Fitzgerald who is also promoting her autobiography. They discuss her ketamine use and move on to talk about Alan's addiction to chocolate, specifically Toblerone.
- In the South Park episode Stupid Spoiled Whore Video Playset (referring to Paris Hilton), the girls say they are going to a party to do Ketamine and then make fun of Wendy for knowing what Ketamine is, saying they have no idea but are going to do it anyway. It is also referred to in the episode You Got F*cked in the Ass where Stan and Chef go to recruit a duck in their dance team. The owner plays two songs for the duck to dance to which contains the line "You do a line and i'll do a line honey" followed by "You snort K and I'll snort K honey".
- Both these South Park episodes have been sampled by STITCH for trax on the BAD SEKTA record label.
- PHUQ released a cdep for BAD SEKTA titled "K Musick [volume one]". His next release is titled "When You Gave Me That Powder You Changed My Life".
- Ketamine is featured also in the episode 44 of the HBO tv-series Six Feet Under, where Russell, one of the students in Claire's art school, reports his experiences after a lengthy trip.
- The band Placebo has a song titled Special K, the content of which is based on the singer's supposed experienced with the drug.
- Ricardo Villalobos, a popular electronic musician affiliated with the microhouse movement, began a unique form of microhouse which eventually came to be called ketamine house.
- Chemical Brothers have a song titled Lost in the K-Hole on their Dig Your Own Hole album.
- The Californian punk band NOFX have a song titled 'Kids of the K Hole' on their 1997 album *So Long and Thanks for All the Shoes*
- CocoRosie, the indie/psych-folk sister duet, has a song called 'K-Hole' on their 2005 album *Noah's Ark* on Touch and Go Records.
- The indie rock group Silver Jews have a song titled 'K-Hole' on their 2005 album *Tanglewood Numbers*.
- The indie pop group The Clientele have songs titled 'Since K Got Over Me' and 'K' on their 2005 album *Strange Geometry*.
- In the movie Cecil B. DeMented, the drug addict character, Lyle, runs in place and shouts "Help! Cherish! I'm stuck in a K-Hole and I can't get out!".
- In the movie Party Monster, starring Macauly Culkin and Seth Green, ketamine was a large part of the main protagonists' downfall.
- In the movie Children of Men, when Julian is talking about when she and Theodore went out to have coffee she refers that his cup was full of ketamine.

- Rock singer Marilyn Manson claims that the experience that resulted from his accidental use of Ketamine (which he mistook for cocaine) inspired the appropriately titled song, 'Disassociative' (from his Mechanical Animals album).

Nitrous oxide, also known as *dinitrogen oxide* or *dinitrogen monoxide*, is a chemical compound with chemical formula N2O. Under room conditions, it is a colourless non-flammable gas, with a pleasant, slightly-sweet odor. It is used in surgery and dentistry for its anaesthetic and analgesic effects, where it is commonly known as *laughing gas* due to the euphoric effects of inhaling it. It is also used as an oxidizer in internal combustion engines. In this use it is known as *nitrous*, or *NOS* after a well-known brand which has become a genericized trademark. Nitrous oxide is present in the atmosphere where it acts as a powerful greenhouse gas.

Chemistry

The structure of the nitrous oxide molecule is a linear chain of a nitrogen atom bound to a second nitrogen atom, which in turn is bound to an oxygen atom. It can be considered a resonance hybrid of *NaN***+***O* and *N=N***+***=O*.

Nitrous oxide, N***2***O, should not be confused with the other oxides of nitrogen such as nitric oxide NO and nitrogen dioxide NO***2***.

Nitrous oxide is isoelectronic with carbon dioxide.

It can be prepared by heating ammonium nitrate in the laboratory and can be used to produce nitrites by mixing it with boiling alkali metals, and to oxidize organic compounds at high temperatures.

The CAS number of nitrous oxide is 10024-97-2 and its UN number is 1070.

History

The gas was discovered by Joseph Priestley in 1772, who called it phlogisticated nitrous air (see phlogiston). Humphry Davy in the 1790s tested the gas on himself and some of his friends, including the poets Samuel Taylor Coleridge and Robert Southey. They soon realised that nitrous oxide considerably dulled the sensation of pain, even if the inhaler were still semi-conscious. And so it came into use as an anaesthetic, particularly by dentists, who do not typically have access to the services of an anesthesiologist and who may benefit from a patient who can respond to verbal commands.

Manufacture

Nitrous oxide is most commonly made by fusing and "boiling" ammonium nitrate to form steam, nitrous oxide, nitrogen, ammonium nitrate 'fog' and small amounts of very toxic higher oxides of nitrogen; (NO_2, NO, etc):

NH_4NO_3 ’ N_2O + $2H_2O$, ”H = 36.8 kJ:

The addition of various phosphates favors formation of a purer gas. This reaction occurs at around 240 °C, a temperature where ammonium nitrate is a moderately sensitive explosive and a very powerful oxidizer (perhaps on the order of fuming nitric acid). At temperatures much above 240 °C the exothermic reaction may run away, perhaps up to the point of detonation. The mixture must be cooled to avoid such a disaster. In practice, the reaction involves a series of tedious adjustments to control the temperature to within a narrow range, which it will not naturally tend to stay in. Professionals have destroyed whole neighborhoods by losing control of such commercial processes. Examples include the Ohio Chemical debacle in Montreal, 1966 and the Air Products & Chemicals, Inc. disaster in Delaware City, Delaware, 1977.

The direct oxidation of ammonia may someday rival the ammonium nitrate pyrolysis synthesis of nitrous oxide mentioned above. This capital-intensive process, which originates in Japan, uses a manganese dioxide-bismuth oxide catalyst. (Suwa et al. 1961; Showa Denka Ltd.)

$2NH_3$ + $2O_2$ ’ N_2O + $3H_2O$:

Higher oxides of nitrogen are formed as impurities. Note that uncatalyzed ammonia oxidation (i.e. combustion or explosion) goes primarily to N2 and H2O. The Ostwald process oxidizes ammonia to nitric oxide (NO), using platinum; this is the beginning of the modern synthesis of nitric acid from ammonia (see above).

Nitrous oxide can be made by heating a solution of sulfamic acids and nitric acids. A lot of gas was made this way in Bulgaria (Brozadzhiew & Rettos, 1975).

HNO_3 + NH_2SO_3H ’ N_2O + H_2SO_4 + H_2O:

There is no explosive hazard in this reaction if the mixing rate is controlled. However, as usual, toxic higher oxides of nitrogen form.

Colorless solutions of hydroxylamine hydrochloride and sodium nitrite may also be used to produce N_2O.

$(NH_3OH+Cl-) + NaNO_2$ ’ $N_2O + NaCl + H_2O$:

If the nitrite is added to the hydroxylamine solution, the gas produced is pure enough for inhalation, and the only remaining byproduct is salt water. However, if the hydroxylamine solution is added to the nitrite solution (nitrite is in excess), then toxic higher oxides of nitrogen form are produced.

Uses

Inhalant effects — laughing gas

Nitrous oxide (N_2O) is a dissociative that can cause analgesia, euphoria, dizziness, flanging of sound, and, in some cases, slight hallucinations and mild aphrodisiac effect.

Aerosol propellant

The gas is licensed for use as a food additive (also known as E942), specifically as an aerosol spray propellant. Its most common uses in this context are in aerosol whipped cream canisters and as an inert gas used to displace staleness-inducing oxygen when filling packages of potato chips and other similar snack foods.

The gas is extremely soluble in fatty compounds. In aerosol whipped cream, it is dissolved in the fatty cream until it leaves the can, when it becomes gaseous and thus creates foam. Used in this way, it produces whipped cream four times the volume of the liquid, whereas whipping air into cream only produces twice the volume. If air were used as a propellant, under increased pressure the oxygen would accelerate rancidification of the butterfat, while nitrous oxide inhibits such degradation.

Rocket motors

Nitrous oxide can be used as an oxidizer in a rocket engine. This has the advantages over other oxidizers that it is non-toxic and, due to its stability at room temperature, easy to store and relatively safe to carry on a flight.

Nitrous oxide has been the oxidizer of choice in several hybrid rocket designs (using solid fuel with a liquid or gaseous oxidizer). The combination of nitrous oxide with hydroxyl-terminated polybutadiene fuel has been used by SpaceShipOne and others. It is also notably used in amateur and high power rocketry with various plastics as the fuel. An episode of MythBusters featured a hybrid rocket built using a paraffin/powdered carbon mixture (and later salami) as its solid fuel and nitrous oxide as its oxidizer.

Nitrous oxide can also be used in a monopropellant rocket. In the presence of a heated catalyst, N2O will decompose exothermically into nitrogen and oxygen, at a temperature of approximately 1300° Celsius. In a vacuum thruster, this can provide a monopropellant specific impulse (Isp) of as much as 180s. While noticeably less than the Isp available from hydrazine thrusters (monopropellant or bipropellant with nitrogen tetroxide), the decreased toxicity makes nitrous oxide an option worth investigating.

Internal combustion engine

In racing, nitrous oxide (often just "nitrous" in this context) is sometimes injected into the intake manifold (or prior to the intake manifold; some systems directly inject it into the cylinder) to increase power: even though the gas itself is not flammable, it delivers more oxygen than atmospheric air by breaking down at elevated temperatures, thus allowing the engine to burn more fuel and air. Additionally, since nitrous oxide is stored as a liquid, the evaporation of liquid nitrous oxide in the intake manifold causes a large drop in intake charge temperature. This results in a denser charge, and can reduce detonation, as well as increase power available to the engine.

The same technique was used during by World War II Luftwaffe aircraft with the GM 1 system to boost the power output of aircraft engines. Originally meant to provide the Luftwaffe standard aircraft with superior high-altitude performance, technological considerations limited its use to extremely high altitudes. Accordingly, it was only used by specialized planes like high-altitude reconnaissance aircraft, high-speed bombers and high-altitude interceptors.

One of the major problems of using nitrous oxide in a reciprocating engine is that it can produce enough power to destroy the engine. Power increases of 100–300% are possible, and unless the mechanical structure of the engine is reinforced, the engine may not survive this kind of operation.

It is very important with nitrous oxide augmentation of internal combustion engines to maintain temperatures and fuel levels so as to prevent preignition, or detonation (sometimes referred to as knocking or pinging).

Safety

The major safety hazards of nitrous oxide come from the fact that it is a compressed liquified gas, and a dissociative anaesthetic.

While normally inert in storage and fairly safe to handle, nitrous oxide can decompose energetically and potentially detonate if initiated under the wrong circumstances. Liquid nitrous oxide acts as a good solvent for many organic compounds; liquid mixtures can form somewhat sensitive explosives. Contamination with fuels has been implicated in a handful of rocketry accidents, where small quantities of nitrous / fuel mixtures detonated, triggering the explosive decomposition of residual nitrous oxide in plumbing.

Nitrous oxide in an atmosphere

Unlike the other Nitrogen oxides, nitrous oxide is a major greenhouse gas; per unit of weight, nitrous oxide has 296 times the effect of carbon dioxide (CO2) for producing global warming. Nitrous oxide is thus part of efforts to curb greenhouse gas emissions, such as the Kyoto Protocol. Behind carbon dioxide and methane, which has 23 times the greenhouse warming potential of carbon dioxide (over 100 years), nitrous oxide is the third most important gas that contributes to global warming. (The other nitrogen oxides contribute to

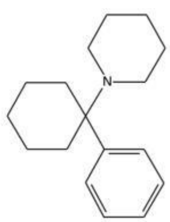
global warming indirectly, by contributing to tropospheric ozone production during smog formation).

Nitrous oxide also attacks ozone in the stratosphere, aggravating the excess amount of UV striking the earth's surface in recent decades (various freons and related halogenated organics also consume ozone in the stratosphere). In the pre-industrial atmosphere nitrous oxide was (and remains) the main natural regulator of stratospheric ozone.

Nitrous oxide is naturally emitted by bacteria in soils and oceans. Agriculture is the main source of human-produced nitrous oxide: cultivating soil, the use of nitrogen fertilizers, and animal waste handling can all stimulate naturally occurring bacteria to produce more nitrous oxide. Industrial sources make up only about 20% of all anthropogenic sources, and include the production of nylon and nitric acid and the burning of fossil fuel in internal combustion engines.

Human activity is thought to account for somewhat less than 2 teragrams (this is multiplied by about 300 when calculated as a ratio to carbon dioxide) of nitrogen oxides per year, nature for over 15 teragram. The global anthropogenic nitrous oxide flux is about 1 petagram of carbon dioxide carbon-equivalents per year; this compares to 2 petagrams of methane carbon dioxide carbon-equivalents per year, and to an atmospheric loading rate of about 3.3 petagrams of carbon dioxide carbon-equivalents per year.

Phencyclidine



Chemical formula $C_{17}H_{25}N$

Molar mass 243.387 g mol1

Systematic name 1-(1-phenylcyclohexyl)piperidine

Phencyclidine (a contraction of the chemical name phenylcyclohexylpiperidine), abbreviated *PCP*, is a dissociative drug formerly used as an anesthetic agent, exhibiting hallucinogenic and neurotoxic effects.

PCP was commercially developed in the 1950s by the Parke-Davis pharmaceutical company. PCP is listed as a Schedule II drug in the United States under the Convention on Psychotropic Substances.[1]

Chemistry and pharmacology

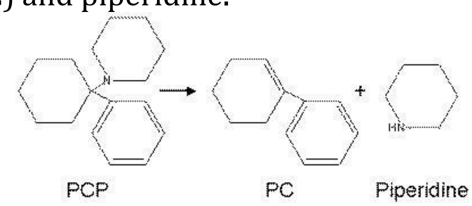
Chemically and pharmacologically it is a member of the family of dissociative anesthetics, which also includes ketamine, tiletamine and high doses of dextromethorphan. Although the primary psychoactive effects of the drug only last hours, total elimination from the body is prolonged, typically extending over weeks.

Toxicology

PCP is a neurotoxin. It is more toxic than other dissociatives and its toxicity is more complex. The damages concern different brain regions and probably affect diverse receptor systems.[2] [3]

Medical and veterinary use

PCP was first tested after World War I as a surgical anaesthetic. Because of its adverse side-effects, it was shelved until the 1950s. It was then patented by Parke-Davis and named Sernyl (supposedly referring to serenity), but was again withdrawn from the market because of side effects. It was soon renamed Sernylan, and marketed as a veterinary anaesthetic, but again discontinued. Its side effects and long half-life in the human body made it unsuitable for medical applications. It is retained in fatty tissue and is broken down by the human metabolism into PCHP, PPC and PCAA. When smoked, some of it is broken down by heat into 1-phenyl-1-cyclohexene (PC) and piperidine.



Recreational use

PCP is consumed recreationally, mainly in the United States[citation needed], where the demand is met by illegal production. The drug is sold in an extremely limited number of cities, such as Washington, DC and Los Angeles[citation needed]. It is available as a liquid (PCP base dissolved most often in ether), but typically it is sprayed onto leafy material such as marijuana, mint, oregano, parsley or Ginger Leaves, and smoked. It is sometimes taken with Ecstasy -- a practice known as "Elephant flipping". PCP is a Schedule II substance in the United States and a Class A substance in Great Britain.

Biochemical action

The N-methyl-D-Aspartate (NMDA) receptor, a type of ionotropic receptor, is found on the dendrites of neurons and receives signals in the form of neurotransmitters. Ingestion of PCP causes prolonged depolarization of the neuron.

Method of absorption

The term "embalming fluid" is often used to refer to the liquid PCP which a cigarette or joint is dipped in, to be ingested through smoking. Smoking PCP is known as "getting wet." There is much confusion over the practice of dipping cigarettes in "embalming fluid" leading some to think that real embalming fluid may actually be used. This is a misconception that may cause serious health consequences beyond those of consuming PCP.

In its powder form, PCP can be insufflated (snorted).

In its pure form, PCP is a white crystalline powder that readily dissolves in water. However, most PCP on the illicit market contains a number of contaminants as a result of makeshift manufacturing, causing the color to range from tan to brown, and the consistency to range from powder to a gummy mass.

Effects

Whether PCP has any strong and consistent effects which are markedly different from other similar compounds is controversial. Some think that the drug's effects are as varied as its appearance. It may be that a moderate amount of PCP will cause users to feel detached, distant, and estranged from their surroundings. Numbness, slurred speech, and loss of coordination may be accompanied by a sense of strength and invulnerability. A blank stare, rapid and involuntary eye movements, diarrhea, and an exaggerated gait are alleged to be among the more observable effects. PCP can sometimes elevate body temperature, which is why many people under the influence of PCP have been known to shed clothing in public places. Acts of violence have been committed by people high on the drug; a well-known example is Brenda Ann Spencer, who claimed to have committed her school massacre while under the influence of alcohol and PCP.

According to the National Institute on Drug Abuse: at high doses of PCP, blood pressure, pulse rate, and respiration drop. This may be accompanied by nausea, vomiting, blurred vision, nystagmus, drooling, loss of balance, and dizziness. High doses of PCP can also cause seizures, coma, and death (though death more often results from accidental injury or suicide during PCP intoxication). High doses can cause symptoms that mimic schizophrenia, such as delusions, hallucinations, paranoia, disordered thinking, a sensation of distance from one's environment, and catatonia. Speech is often sparse and garbled.

References in Popular Culture

- More so than any other illegal substance, PCP has developed an elaborate mythological history surrounding itself, spread by sources such as

D.A.R.E. PCP is said in an urban legend to cause intensely realistic hallucinations, e.g. of spiders engulfing the user's face, causing the user to injure himself in an attempt to remove them. In reality such effects are more like those of a deliriant.

- Among police and firefighters, PCP is treated as a menace. Individuals on PCP are treated almost as bogey-men in personal safety lectures that are loaded with stories involving people on PCP chasing down cars and breaking through walls because they are unable to feel pain.
- One of the street thugs in the Charles Bronson film Death Wish II was portrayed as a PCP user - the scene where he assaults several police officers is reminiscent of an NFL wide receiver evading linemen.
- Another famous mention is in the movie Terminator, where the violent attacks by the character played by Arnold Schwarzenegger, including punching through a windshield without feeling it, are attributed to PCP by the police.
- In an NCIS episode, a supermodel was found dead with PCP in her system.
- In 1981's "Angel Dusted", and again in 1982's "Desperate Lives", characters played by actress Helen Hunt tangle with PCP. After taking PCP in "Angel Dusted", she jumps out a closed second-story window and then gets up and starts scraping her arm violently with a shard of glass.
- American Musician Antron Singleton committed murder and cannibalism while under the effects of PCP.
- On Chappelle's Show, Dave Chappelle is offered PCP by Wayne Brady, which Dave refuses until he is threatened by Wayne (this being a parallel to the movie Training Day.) PCP references abound in the series (perhaps because of Chappelle's upbringing in Washington, D.C., which as mentioned above, is one of the few PCP epicenters in the US)--The World Series of Dice is played by a diceman, Grits n' Gravy, who spends all his winnings on PCP. In the same sketch, one of the characters is named "Ashy Larry," which is slang for PCP. The "angel" in the sketch "It's A Wonderful Chest" attributes his powers to PCP. Also, the character Tyrone Biggums, in his first appearance on the show when he visits a classroom full of schoolchildren to tell them of the dangers of drug use, mentions that he has smoked marijuana laced with "embalming fluid" (see above).
- In the 1995 film "Friday", Chris Tucker's character Smokey mistakenly smokes PCP and develops a twitch that he carries throughout the movie.
- Faith No More has an album titled Angel Dust. It was released in 1992.
- Butthole Surfers released the Live PCPEP in 1984.
- The popular Jackass cast member "Steve-O" documented his 5-day 'trip' on PCP on his DVD "PCP Saved my Life". He precedes the showing of the tape with an announcement, saying he will never watch the tape of his 'trip', and that he will never take PCP again, he remembers no part of the 5-day trip in which he frequently proclaims that PCP has saved his life.
- In Thomas Harris' novel Hannibal, it is described that one of Hannibal Lecter's victims, Mason Verger, performed self-mutilation whilst under the influence of phencyclidine and other drugs that Lecter drugged him with.

- In the second season of the television show Buffy the Vampire Slayer, in the episode School Hard, the principal of the high school covers up a vampire attack by claiming that the attackers were "gang members on PCP."
- In the first manga episodes of City Hunter, Ryo Saeba confronts a syndicated crime group called Union Theope, which uses phencyclidine on some of its agents in order to make them more invulnerable.
- In the 1983 movie Trading Places, Dan Aykroyd is framed for selling PCP.
- 'The Simpsons' featured an episode in which Marge is incorrectly drug-tested positive for "crack and PCP".
- Tupac Shakur mentions PCP in his song "I Ain't Mad at Ya" - "...standin' on the block, wit ya glock, trippin' off sherm..." He also mentioned it in "Hit 'Em Up" - "Smokin' dope, it's like a sherm high/niggas think they learned to fly" and Me & My Girlfriend -"Smokin' sherm drinking malt liquor/father forgive her" (As noted above, "sherm" is a slang name for PCP.)
- Notorious BIG refers to PCP in his song Notorious Thugs and its remix Spit Your Game- "Ain't too many can bang with us/straight up weed no angel dust". He also refers to it in 'Gimme the Loot' - Crazier than a bag of fucking angel dust.
- In Jonathan Caouette's film "Tarnation", he is said to have smoked a PCP-laced joint as a teenager.
- In the System of a Down song "Stealing Society" from the album Hypnotize there is a lyric "crack pipes, needles, PCP and fast cars, kinda mix really well with a dead movie star."
- In the Beastie Boys song "3 Minute Rule" from the album Paul's Boutique there are lyrics by Adrock in which he says, "so peace out y'all, I'm PCP, so I'm out, full throttle to the bottle and full full clout, and I'm out." The Beastie Boys often refer to being 'dusted' in their lyrics, slang for being high on PCP.
- PCP was seen on the television show COPS when a bleeding, naked man punched a hole in a fence and was tackled by many police officers.
- The punk band NOFX released a song on the "Fuck the Kids" album - Eric Melvin VS PCP. Eric Melvin being the bands guitarist.
- The British pop band Right Said Fred released a song named "Angel Dust" on their 2001 album "Fredhead", in which a woman is compared to the effects of the drug.
- In episode 49, the third episode of the third season, of CSI a high school student kills and eats parts of another girl while under the effects of PCP.
- Ghostface Killah often references PCP in his songs such as in Who Are We "...see me in New Orleans, start puffin' on 'sherm" in Apollo Kids "...two culture-ciphers, one bag of wet", the song Ghostface "...now Daddy's blowin' sherm and Remi".
- The British Rock/Electronic band New Order had a track called "Angel Dust" on their Brotherhood album.

- Mitch Hedberg used a joke in which he elaborated on a physical he was required to take to perform on Comedy Central Presents. "To do this show I had to take a physical. They asked me a bunch of medical questions, and they were like, yes or no questions, but they were very strangely worded. Like 'Have you ever tried sugar... or PCP?"
- Calling themselves the "Leak Bros.", rappers Tame One and Cage released an album entitled Waterworld in 2005 on Eastern Conference Records. The entire album was devoted to PCP. "Leak" or "Leaky Leak" is slang for PCP laced marijuana.
- In the popular urban movie Training Day, Ethan Hawke's character smokes marijuana laced with PCP and goes into a stupor-like dream state where everything slows down and the environment changes color.
- Welsh rock band Manic Street Preachers have a song called P.C.P., released as part of a double A-side single, and on their album The Holy Bible. The British metal band Venom released a song named "Angel Dust"
- The PCP in a game called XEvil actually does cause temporary invulnerability and increased strength. However, abusing the drug causes death by overdose. There is a German power metal band named Angel Dust.

Anti-diabetic drugs

An *anti-diabetic drug* or *oral hypoglycemic agent* is used to treat diabetes mellitus. They usually work by lowering the glucose levels in the blood. There are different types of anti-diabetic drugs, and their use depends on the nature of the diabetes, age and situation of the person, as well as other factors.

Insulin, exenatide, and pramlintide are the only non-oral antidiabetic drugs. Insulin is the mainstay of treatment in Type I diabetes, in which insulin production is impaired. In Type II diabetes, Insulin is used when oral medication has become ineffective. Exenatide and pramlintide are new injectable medications approved in 2005 in the US by the FDA to treat Diabetes mellitus type 2.

Diabetes mellitus

Types of Diabetes

Diabetes mellitus type 1

Diabetes mellitus type 2

Gestational diabetes

Pre-diabetes:
Impaired fasting glycaemia
Impaired glucose tolerance

Disease Management

Diabetes management:

•Diabetic diet

•**Anti-diabetic drugs**

•Conventional insulinotherapy

•Intensive insulinotherapy

Blood tests

Fructosamine

Glucose tolerance test

Glycosylated hemoglobin

Sulfonylureas

Sulfonylureas were the first widely used oral hypoglycemic medications. They are insulin secretagogues, triggering insulin release by direct action on the K***ATP*** channel of the pancreatic beta cells. Eight types of these pills have been marketed in North America, but not all remain available. The "second-generation" drugs are now more commonly used. They are more effective than first-generation drugs and have fewer side effects.

Sulfonylureas bind strongly to plasma proteins. Sulfonylureas are only useful in Type II diabetes, as they work by stimulating endogenous release of insulin. They work best with patients over 40 years old, who have had diabetes mellitus for under ten years. They can not be used with type I diabetes, or diabetes of pregnancy. They can be safely used with metformin or -glitazones. The primary side effect is hypoglycemia.

- First-generation agents
  - tolbutamide (Orinase)

acetohexamide (Dymelor)
tolazamide (Tolinase)
chlorpropamide (Diabinese)

- Second-generation agents
  - glipizide (Glucotrol)

glyburide (Diabeta, Micronase, Glynase)
glimepiride (Amaryl)
gliclazide (Diamicron)

Meglitinides

Meglitinides are related to sulfonylureas and of often called "short-acting secretagogues." The amplification of insulin release is shorter and more intense, and they are taken with meals to boost the insulin response to each meal.

- repaglinide (Prandin) - The max dosage is 16mg/day. Take this drug 0 to 30 minutes prior before eating a meal. If a meal is skipped, then the medication should also be skipped.
- nateglinide (Starlix) - The max dosage is 360 mg/day, usually 120 mg three times a day (TID). It also follows the same recommendations as repaglinide.

Adverse reactions include weight gain and hypoglycemia.

Biguanides

Biguanides reduce hepatic glucose output and increase uptake of glucose by the periphery, including skeletal muscle. Although it must be used with caution in patients with impaired liver or kidney function, metformin has become the most commonly used agent for type 2 diabetes in children and teenagers.

- metformin (Glucophage)
- Phenformin (DBI): used in 1960-1980s, withdrawn due to lactic acidosis risk.

Metformin should be temporarily discontinued before any radiographic procedure involving intravenous iodinated contrast as patients are at an increased risk of lactic acidosis.

Thiazolidinediones

Thiazolidinediones, also known as "glitazones," bind to PPAR[3], a type of nuclear regulatory protein involved in transcription of numerous genes regulating glucose and fat metabolism. They act as "insulin sensitizers" without increasing insulin secretion.

- rosiglitazone (Avandia)

pioglitazone (Actos)
troglitazone (Rezulin): used in 1990s, withdrawn due to hepatitis and liver damage risk.

Alpha glucosidase inhibitors

Alpha glucosidase inhibitors are "diabetes pills" but not technically hypoglycemic agents because they do not have a direct effect on insulin secretion or sensitivity. These agents slow the digestion of starch in the small intestine, so that glucose from the starch of a meal enters the bloodstream more slowly, and can be matched more effectively by an impaired insulin response or sensitivity. These agents are effective by themselves only in the earliest stages of impaired glucose tolerance, but can be helpful in combination with other agents in type 2 diabetes.

- miglitol (Glyset)
acarbose (Precose/Glucobay)

These medications are rarely used in the United States because of the severity of their side effects (flatulence and bloating). They are more commonly prescribed in Europe.

Incretin mimetic

Exenatide (also Exendin-4, marketed as Byetta) is the first of a new class of medications approved for the treatment of type 2 diabetes. It is to be used in conjunction with oral medications such as metformin and/or a sulfonylurea to improve glucose control. The medication is injected twice per day using a specially designed pen. The typical human response is both an improvement of the release of internal insulin by the pancreas and suppression of pancreas glucagon release, behaviors more typical of individuals without blood sugar control problems. In the presence of exenatide, these responses are greater when the blood sugar is elevated.

DPP-4 inhibitors

- Dipeptidyl peptidase-4 (DPP-4) inhibitors (vildagliptin, sitagliptin) increase blood concentration of GLP-1 (glucagon-like peptide-1).

Amylin analogue

- Pramlintide.

Experimental agents

Many other potential drugs are currently in investigation by pharmaceutical companies. Some of these are simply newer members of one of the above classes, but some work by novel mechanisms. For example, at least one compound that enhances the sensitivity of glucokinase to rising glucose is in the stage of animal research. Others are undergoing phase I/II studies.

- PPAR±/³ ligands (muraglitazar and tesaglitazar) - development stopped due to adverse risk profile
- SGLT (sodium-dependent glucose transporter 1) inhibitors increase urinary glucose.
- FBPase (fructose 1,6-bisphosphatase) inhibitors decrease gluconeogenesis in liver.

Insulin by mouth

The basic appeal of oral hypoglycemic agents is that most people would prefer a pill to an injection. Unlike all the oral drugs described in this article, insulin is a protein. Protein hormones, like meat proteins, are digested in the stomach and gut. One alternative delivery

method is by inhalation. In 2006 the U.S. Food and Drug Administration approved the use of Exubera, the first inhalable insulin.

However, the potential market for an oral form of insulin is enormous and many laboratories have attempted to devise ways of moving enough intact insulin from the gut to the portal vein to have a measurable effect on blood sugar. One can find several research reports over the years describing promising approaches or limited success in animals, and limited human testing, but as of 2004, no products appear to be successful enough to bring to market.

Herbal extracts

The first registred use of anti-diabetic drugs was as herbal extracts used by indians in the Amazon Basin for the treatment of type 2 diabetes, and today promoted as vegetable insulin although not formally an insulin analog.[1] The major recent development was done in Brazil around Myrcia sphaerocarpa and other Myrcia species.

"Many countries, especially in the developing world, have a long history of the use of herbal remedies in diabetes (...) STZ diabetic rats were also used to test Myrcia Uniflora extracts (...) "[2].

The usual treatment is with concentrated (root) Myrcia extracts, commercialized in a 4 US dollar per kilogram packed rocks (~100 times cheaper than equivalent artificial drugs), named "Pedra hume de kaá". Phytochemical analysis of the Myrcia extracts reported kinds of flavanone glucosides (myrciacitrins) and acetophenone glucosides (myrciaphenones), and inhibitory activities on aldose reductase and alpha-glucosidase.[3]

A recent review article presents the profiles of plants with hypoglycaemic properties, reported in the literature from 1990 to 2000 and states that "Medical plants play an important role in the management of diabetes mellitus especially in developing countries where resources are meager."[4]

Diabetes mellitus is a disorder of metabolism, most prominently carbohydrate metabolism. It is a disease characterized by persistent hyperglycemia (high glucose blood sugar). It is a metabolic disease that requires medical diagnosis, treatment and lifestyle changes. The World Health Organization recognizes three main forms of diabetes: type 1, type 2 and gestational diabetes (or type 3, occurring during pregnancy)[1], although these three "types" of diabetes are more accurately considered patterns of pancreatic failure rather than single diseases. Type 1 is generally due to autoimmune destruction of the insulin-producing cells, while type 2 and gestational diabetes are due to insulin resistance by tissues. Type 2 may progress to destruction of the insulin-producing cells of the pancreas, but is still considered Type 2, even though insulin administration may be required.

Since the first therapeutic use of insulin (1921) diabetes has been a treatable but chronic condition, and the main risks to health are its characteristic long-term complications. These include cardiovascular disease (doubled risk), chronic renal failure (it is the main cause for dialysis in developed world adults), retinal damage which can lead to blindness and is the most significant cause of adult blindness in the non-elderly in the developed world, nerve damage, erectile dysfunction (impotence) and gangrene with risk of amputation of toes, feet, and even legs.

Terminology

The term diabetes (Greek: ´¹±²®Ä·Â) was coined by Aretaeus of Cappadocia. It is derived from the Greek ´¹±²±¯½µ¹½, diabaínein that literally means "passing through," or "siphon," a reference to one of diabetes' major symptoms—excessive urine production. In 1675 Thomas Willis added mellitus from the Latin word for honey (mel in the sense of "honey sweet") when he noted that the blood and urine of a diabetic has a sweet taste. This had been noticed long before in ancient times by the Greeks, Chinese, Egyptians, and Indians. In 1776 Matthew Dobson confirmed the sweet taste was because of an excess of a kind of sugar in the urine and blood of people with diabetes.[2]

The ancient Indians tested for diabetes by observing whether ants were attracted to a person's urine, and called the ailment "sweet urine disease" (Madhumehalai); medieval European doctors tested for it by tasting the urine themselves, a scene which was occasionally depicted in Gothic reliefs.

While the term diabetes without a modifier usually refers to diabetes mellitus, there is another, rarer condition named diabetes insipidus (unquenchable diabetes) in which the urine is not sweet; it can be caused by either kidney (nephrogenic DI) or pituitary gland (central DI) damage.

History

Although diabetes has been recognized since antiquity, and treatments of various efficacy have been known in various regions since the Middle Ages, and in legend for much longer, the elucidation of the pathogenesis of diabetes occurred mainly in the 20th century.[3] The discovery of the role of the pancreas in diabetes is generally ascribed to Joseph von Mering and Oskar Minkowski, European researchers who in 1889 found that when they completely removed the pancreas of dogs, the dogs developed all the signs and symptoms of diabetes and died shortly afterward.[4] In 1910, Sir Edward Albert Sharpey-Schafer of Edinburgh suggested that people with diabetes were deficient in a single chemical that was normally produced by the pancreas—he proposed calling this substance insulin. The term is derived from the Latin insula, meaning island, in reference to the islets of Langerhans in the pancreas that produce insulin.[3]

The endocrine role of the pancreas in metabolism, and indeed the existence of insulin, was not fully clarified until 1921, when Sir Frederick Grant Banting and Charles Herbert Best repeated the work of Von Mering and Minkowski, but went further and demonstrated that they could reverse induced diabetes in dogs by giving them an extract from the pancreatic islets of Langerhans of healthy dogs.[5] Banting, Best, and colleagues (particularly the chemist Collip) went on to isolate the hormone insulin from bovine pancreases at the University of Toronto in Canada. This led to the availability of an effective treatment—insulin injections—and the first clinical patient was treated in 1922. For this, Banting and MacLeod received the Nobel Prize in Physiology or Medicine in 1923; both shared their Prize money with others in the team who were not recognized, in particular Best and Collip. Banting and Best made the patent available without charge and did not attempt to control commercial production. Insulin production and therapy rapidly spread around the world, largely as a result of this decision.

Despite the availability of treatment, diabetes remained a major cause of death. For instance, statistics reveal that the cause-specific mortality rate during 1927 amounted to about 47.7 per 100,000 population in Malta.[6]

The distinction between what is now known as type 1 diabetes and type 2 diabetes was first clearly made by Sir Harold Percival (Harry) Himsworth in 1935 and was published in January 1936.[7]

Other landmark discoveries include:[3]

- identification of the first of the sulfonylureas in 1942
the radioimmunoassay for insulin, as discovered by Rosalyn Yalow and Solomon Berson (gaining Yalow the 1977 Nobel Prize in Physiology or Medicine)[8]

Dr Gerald Reaven's identification of the constellation of symptoms now called metabolic syndrome in 1988
Demonstration that intensive glycemic control in type 1 diabetes reduces chronic side effects more as glucose levels approach 'normal' in a large longitudinal study[9], and also in type 2 diabetics in other large studies
identification of the first thiazolidinedione as an effective insulin sensitizer during the 1990's
Self monitoring of glucose in the home via a finger-stick blood sample and a battery powered meter in the 1970's.[10]

Causes & types

Glucose metabolism

Since insulin is the principal hormone that regulates uptake of glucose into most cells from the blood (primarily muscle and fat cells, but not central nervous system cells), deficiency of insulin or the insensitivity of its receptors plays a central role in all forms of diabetes mellitus.

Much of the carbohydrate in food is converted within a few hours to the monosaccharide glucose, the principal carbohydrate in blood. Some carbohydrates are not; fruit sugar (fructose) is usable as cellular fuel but is not converted to glucose and does not participate in the insulin / glucose metabolic regulatory mechanism, nor does the carbohydrate cellulose (though it is actually many glucoses in long chains) as humans and many animals have no digestive pathway capable of handling it. Insulin is released into the blood by beta cells (^{2}-cells) in the pancreas in response to rising levels of blood glucose (e.g., after a meal). Insulin enables most body cells (about 2/3 is the usual estimate, including muscle cells and adipose tissue) to absorb glucose from the blood for use as fuel, for conversion to other needed molecules, or for storage. Insulin is also the principal control signal for conversion of glucose (the basic sugar used for fuel) to glycogen for internal storage in liver and muscle cells. Reduced insulin levels result both in the reduced release of insulin from the beta cells and in the reverse conversion of glycogen to glucose when glucose levels fall, although only glucose thus recovered by the liver re-enters the bloodstream as muscle cells lack the necessary export mechanism.

Higher insulin levels increase many anabolic ("building up") processes such as cell growth and duplication, protein synthesis, and fat storage. Insulin is the principal signal in converting many of the bidirectional processes of metabolism from a catabolic to an anabolic direction, and vice versa. In particular, it is the trigger for entering or leaving ketosis (ie, the fat burning metabolic phase).

If the amount of insulin available is insufficient, if cells respond poorly to the effects of insulin (insulin insensitivity or resistance), or if the insulin itself is defective, glucose will not be handled properly by body cells (about T require it) or stored appropriately in the liver and muscles. The net effect is persistent high levels of blood glucose, poor protein synthesis, and other metabolic derangements, such as acidosis.

Type 1 diabetes mellitus

Type 1 diabetes mellitus - formerly known as insulin-dependent diabetes (IDDM), childhood diabetes, or juvenile-onset diabetes - is characterized by loss of the insulin-producing beta cells of the islets of Langerhans of the pancreas leading to a deficiency of insulin. Sensitivity and responsiveness to insulin are usually normal, especially in the early stages. This type comprises up to 10% of total cases in North America and Europe, though this varies by geographical location. This type of diabetes can affect children or adults, but has traditionally been termed "juvenile diabetes" because it represents a majority of cases of diabetes affecting children. The most common cause of beta cell loss leading to type 1 diabetes is autoimmune destruction, accompanied by antibodies directed against insulin and islet cell proteins. The principal treatment of type 1 diabetes, even from the earliest stages, is replacement of insulin. Without insulin, ketosis and diabetic ketoacidosis can develop and coma or death will result.

Currently, type 1 diabetes can be treated only with insulin, with careful monitoring of blood glucose levels using blood testing monitors. Emphasis is also placed on lifestyle adjustments (diet and exercise). Apart from the common subcutaneous injections, it is also possible to deliver insulin via a pump, which allows infusion of insulin 24 hours a day at preset levels, and the ability to program a push dose (a bolus) of insulin as needed at meal times. This is at the expense of an indwelling subcutaneous catheter. It is also possible to deliver insulin via an inhaled powder.

Type 1 treatment must be continued indefinitely at present. Treatment does not impair normal activities, if sufficient awareness, appropriate care, and discipline in testing and medication. The average glucose level for the type 1 patient should be as close to normal (80–120 mg/dl, 4–6 mmol/l) as possible. Some physicians suggest up to 140–150 mg/dl (7-7.5 mmol/l) for those having trouble with lower values, such as frequent hypoglycemic events. Values above 200 mg/dl (10 mmol/l) are often accompanied by discomfort and frequent urination leading to dehydration. Values above 300 mg/dl (15 mmol/l) usually require immediate treatment and may lead to ketoacidosis. Low levels of blood glucose, called hypoglycemia, may lead to seizures or episodes of unconsciousness.

Type 2 diabetes mellitus

Type 2 diabetes mellitus - previously known as adult-onset diabetes, maturity-onset diabetes, or non-insulin dependent diabetes mellitus (NIDDM) - is due to a combination of defective insulin secretion and defective responsiveness to insulin (often termed insulin resistance or reduced insulin sensitivity), almost certainly involving the insulin receptor in cell membranes. In early stages, the predominant abnormality is reduced insulin sensitivity, characterized by elevated levels of insulin in the blood. In the early stages, hyperglycemia can be reversed by a variety of measures and medications that improve insulin sensitivity or reduce glucose production by the liver, but as the disease progresses the impairment of insulin secretion worsens, and therapeutic replacement of insulin often becomes necessary. There are numerous theories as to the exact cause and mechanism for this resistance, but central obesity (fat concentrated around the waist in relation to abdominal organs, not it

seems, subcutaneous fat) is known to predispose for insulin resistance, possibly due to its secretion of adipokines (a group of hormones) that impair glucose tolerance. Abdominal fat is especially active hormonally. Obesity is found in approximately 90% of Developed world patients diagnosed with type 2 diabetes. Other factors may include aging and family history, although in the last decade it has increasingly begun to affect children and adolescents.

Type 2 diabetes may go unnoticed for years in a patient before diagnosis, since the symptoms are typically milder (e.g. lack of ketoacidotic episodes) and can be sporadic. However, severe complications can result from unnoticed type 2 diabetes, including renal failure, vascular disease (including coronary artery disease), vision damage, etc.

Type 2 diabetes is usually first treated by changes in physical activity (usually increase), diet (generally decrease carbohydrate intake, especially glucose generating carbohydrates), and through weight loss. These can restore insulin sensitivity, even when the weight loss is modest, for example, around 5 kg (10 to 15 lb), most especially when it is in abdominal fat deposits. The next step, if necessary, is treatment with oral antidiabetic drugs. As insulin production is initially unimpaired, oral medication (often used in combination) can still be used that improves insulin production (eg, sulfonylureas) and regulate inappropriate release of glucose by the liver (and attenuate insulin resistance to some extent (eg, metformin), and substantially attenuate insulin resistance (eg, thiazolidinediones). If these fail, insulin therapy will be necessary to maintain normal or near normal glucose levels. A disciplined regimen of blood glucose checks is recommended in most cases, most particularly and necessarily when taking most of these medications.

Gestational diabetes

Gestational diabetes, Type 3, also involves a combination of inadequate insulin secretion and responsiveness, resembling type 2 diabetes in several respects. It develops during pregnancy and may improve or disappear after delivery. Even though it may be transient, gestational diabetes may damage the health of the fetus or mother, and about 20%–50% of women with gestational diabetes develop type 2 diabetes later in life.

Gestational diabetes mellitus occurs in about 2%–5% of all pregnancies. It is temporary, and fully treatable, but, if untreated, may cause problems with the pregnancy, including macrosomia (high birth weight) of the child. It requires careful medical supervision during the pregnancy.

Other types

There are several rare causes of diabetes mellitus that do not fit into type 1, type 2, or gestational diabetes:

- Genetic defects in beta cells (autosomal or mitochondrial)
- Genetically-related insulin resistance, with or without lipodystrophy (abnormal body fat deposition)
- Diseases of the pancreas (e.g. chronic pancreatitis, cystic fibrosis)
- Hormonal defects
- Chemicals or drugs

The tenth version of the International Statistical Classification of Diseases (ICD-10) contained a diagnostic entity named "malnutrition-related diabetes mellitus" (MRDM or MMDM, ICD-10 code E12). A subsequent WHO 1999 working group recommended that MRDM be deprecated, and proposed a new taxonomy for alternative forms of diabetes.[1] Classifications of non-type 1, non-type 2, non-gestational diabetes remains controversial.

Genetics

Both type 1 and type 2 diabetes are at least partly inherited. Type 1 diabetes appears to be triggered by some (mainly viral) infections, or in a less common group, by stress or environmental factors (such as exposure to certain chemicals or drugs). There is a genetic element in individual susceptibility to some of these triggers which has been traced to particular HLA genotypes (i.e. genetic "self" identifiers used by the immune system). However, even in those who have inherited the susceptibility, type 1 diabetes mellitus seems to require an environmental trigger. A small proportion of people with type 1 diabetes carry a mutated gene that causes maturity onset diabetes of the young (MODY).

There is a rather stronger inheritance pattern for type 2 diabetes. Those with first-degree relatives with type 2 have a much higher risk of developing type 2. Concordance among monozygotic twins is close to 100% , and 25% of those with the disease have a family history of diabetes. It is also often connected to obesity, which is found in approximately 85% of (North American) patients diagnosed with this type, so some experts believe that inheriting a tendency toward obesity also contributes.

Diagnosis

Signs and symptoms

The classical triad of diabetes symptoms is polyuria (frequent urination), polydipsia (increased thirst, and consequent increased fluid intake) and polyphagia (increased appetite). These symptoms may develop quite fast in type 1, particularly in children (weeks or months), but may be subtle or completely absent - as well as developing much more slowly - in type 2. In type 1 there may also be weight loss (despite normal or increased eating), increased appetite, and irreducible fatigue. These symptoms may also manifest in type 2 diabetes in patients whose diabetes is poorly controlled.

Thirst develops because of osmotic effects—sufficiently high glucose (above the "renal threshold") in the blood is excreted by the kidneys, but this requires water to carry it and causes increased fluid loss, which must be replaced. The lost blood volume will be replaced from water held inside body cells, causing dehydration. Prolonged high blood glucose causes changes in the shape of the lens in the eye, leading to vision changes. Blurred vision is a common complaint leading to a diagnosis of type 1; it should always be suspected in such cases.

Patients (usually with type 1 diabetes) may also present with diabetic ketoacidosis (DKA), an extreme state of dysregulation characterized by the smell of acetone on the patient's breath, Kussmaul breathing (a rapid, deep breathing), polyuria, nausea, vomiting

and abdominal pain and any of many altered state of consciousness or arousal (eg, hostility and mania or, equally, confusion and lethargy). In severe DKA, coma (unconsciousness) may follow, progressing to death if untreated. In any form, DKA is a medical emergency and requires expert attention.

A rarer but equally severe presentation is hyperosmolar nonketotic state, which is more common in type 2 diabetes, and is mainly the result of dehydration due to the polyuria. Often, the patient has been drinking extreme amounts of sugar-containing drinks, leading to a vicious circle in regard to water loss.

Diagnostic approach

The diagnosis of type 1 diabetes and many cases of type 2 is usually prompted by recent-onset symptoms of excessive urination (polyuria) and excessive thirst (polydipsia), often accompanied by weight loss. These symptoms typically worsen over days to weeks; about 25% of people with new type 1 diabetes have developed a degree of diabetic ketoacidosis by the time the diabetes is recognized. The diagnosis of other types of diabetes is usually made in many other ways. The most common are (1) health screening, (2) detection of hyperglycemia when a doctor is investigating a complication of longstanding, unrecognized diabetes, and (3) new signs and symptoms attributable to the diabetes.

1. Diabetes screening is recommended for many types of people at various stages of life or with several different risk factors. The screening test varies according to circumstances and local policy and may be a random glucose, a fasting glucose and insulin, a glucose two hours after 75 g of glucose, or a formal glucose tolerance test. Many healthcare providers recommend universal screening for adults at age 40 or 50, and sometimes occasionally thereafter. Earlier screening is recommended for those with risk factors such as obesity, family history of diabetes, high-risk ethnicity (Hispanic/Latin American, American Indian, African American, Pacific Island, and South Asian ancestry).
2. Many medical conditions are associated with a higher risk of various types of diabetes and warrant screening. A partial list includes: high blood pressure,
3. elevated cholesterol levels, coronary artery disease, past gestational diabetes, polycystic ovary syndrome, chronic pancreatitis, fatty liver, hemochromatosis, cystic fibrosis, several mitochondrial neuropathies and myopathies, myotonic dystrophy, Friedreich's ataxia, some of the inherited forms of neonatal hyperinsulinism, and many others. Risk of diabetes is higher with chronic use of several medications, including high-dose glucocorticoids, some chemotherapy agents (especially L-asparaginase), and some of the antipsychotics and mood stabilizers (especially phenothiazines and some atypical antipsychotics).
Diabetes is often detected when a person suffers a problem frequently caused by diabetes, such as a heart attack, stroke, neuropathy, poor wound healing or a foot ulcer, certain eye problems, certain fungal infections, or delivering a baby with macrosomia or hypoglycemia.

Diagnostic criteria

Diabetes mellitus is characterized by recurrent or persistent hyperglycemia, and is diagnosed by demonstrating any one of the following:[1]

- fasting plasma glucose level at or above 126 mg/dL or 7.0 mmol/l.
- plasma glucose at or above 200 mg/dL or 11.1 mmol/l two hours after a 75 g oral glucose load in a glucose tolerance test.
- random plasma glucose at or above 200 mg/dL or 11.1 mmol/l.

A positive result should be confirmed by any of the above-listed methods on a different day, unless there is no doubt as to the presence of significantly-elevated glucose levels. Most physicians prefer measuring a fasting glucose level because of the ease of measurement and time commitment of formal glucose tolerance testing, which can take two hours to complete. By definition, two fasting glucose measurements above 126 mg/dL or 7.0 mmol/l is considered diagnostic for diabetes mellitus.

Patients with fasting sugars between 6.1 and 7.0 mmol/l (110 and 125 mg/dL) are considered to have "impaired fasting glucose" and patients with plasma glucose at or above 140mg/dL or 7.8 mmol/l two hours after a 75 g oral glucose load are considered to have "impaired glucose tolerance". "Prediabetes" is either impaired fasting glucose or impaired glucose tolerance; the latter in particular is a major risk factor for progression to full-blown diabetes mellitus as well as cardiovascular disease.

While not used for diagnosis, an elevated level of glucose bound to hemoglobin (termed glycosylated hemoglobin or HbA1c) of 6.0% or higher (2003 revised U.S. standard) is considered abnormal by most labs; HbA1c is primarily a treatment-tracking test reflecting average blood glucose levels over the preceding 90 days (approximately). However, some physicians may order this test at the time of diagnosis to track changes over time. The current recommended goal for HbA1c in patients with diabetes is <7.0%, as defined as "good glycemic control", although some guidelines are stricter (<6.5%). People with diabetes that have HbA1c levels within this goal have a significantly lower incidence of complications from diabetes, including retinopathy and diabetic nephropathy.[11]

Complications

The complications are far less common and less severe in people who have well-controlled blood sugar levels.[12] [13] In fact, the better the control, the lower the risk of complications. Hence patient education, understanding and participation is vital. Healthcare professionals who treat diabetes also address other health problems that may accelerate the deleterious effects of diabetes. These include smoking (abstain), elevated cholesterol levels (control with diet, exercise or medication), obesity (even modest weight loss can be beneficial), high blood pressure, and lack of regular exercise.

Acute

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is an acute, dangerous complication and is always a medical emergency. On presentation at hospital, the patient in DKA is typically dehydrated and breathing both fast and deeply. Abdominal pain is common and may be severe. The level of consciousness is normal until late in the process, when lethargy (dulled or reduced level of alertness or consciousness) may progress to coma. The ketoacidosis can become severe enough to cause hypotension and shock. Prompt proper treatment usually results in full recovery, though death can result from inadequate treatment, delayed treatment or from a variety of complications. It is much more common in type 1 diabetes than type 2, but can still occur in patients with type 2 diabetes.

Nonketotic hyperosmolar coma

While not always progressing to coma, this hyperosmolar nonketotic state (HNS) is another acute problem associated with diabetes mellitus. It has many symptoms in common with DKA, but a different cause, and requires different treatment. In anyone with very high blood glucose levels (usually considered to be above 300 mg/dl or 16 mmol/l), water will be osmotically driven out of cells into the blood. The kidneys will also be "dumping" glucose into the urine, resulting in concomitant loss of water, causing an increase in blood osmolality. If the fluid is not replaced (by mouth or intravenously), the osmotic effect of high glucose levels combined with the loss of water will eventually result in such a high serum osmolality (dehydration). The body's cells may become progressively dehydrated as water is drawn out from them and excreted. Electrolyte imbalances are also common. This combination of changes, especially if prolonged, will result in symptoms of lethargy (dulled or reduced level of alertness or consciousness) and may progress to coma. As with DKA urgent medical treatment is necessary, especially volume replacement. This is the diabetic coma which more commonly occurs in type 2 diabetics.

Hypoglycemia

Hypoglycemia, or abnormally low blood glucose, is a complication of several diabetes treatments. It may develop if the glucose intake does not match the treatment. The patient may become agitated, sweaty, and have many symptoms of sympathetic activation of the autonomic nervous system resulting in feelings similar to dread and immobilized panic. Consciousness can be altered, or even lost, in extreme cases, leading to coma and/or seizures or even brain damage and death. In patients with diabetes this can be caused by several factors, such as too much or incorrectly timed insulin, too much exercise or incorrectly timed exercise (which decreases insulin requirements) or not enough food or insufficient amount of carbohydrates in food. In most cases, hypoglycemia is treated with sweet drinks or food. In severe cases, an injection of glucagon (a hormone with the opposite effects of insulin) or an intravenous infusion of glucose is used for treatment, but usually only if the diabetic is unconscious.

Chronic

Microvascular disease

Chronic elevation of blood glucose level leads to damage of blood vessels. In diabetes, the resultant problems are grouped under "microvascular disease" (due to damage to small blood vessels) and "macrovascular disease" (due to damage to the arteries).

The damage to small blood vessels leads to a microangiopathy, which causes the following organ-related problems:

- Diabetic retinopathy, growth of friable and poor-quality new blood vessels in the retina as well as macular edema (swelling of the macula), which can lead to severe vision loss or blindness. Retinal damage (from microangiopathy) makes it the most common cause of blindness among non-elderly adults in the US.
- Diabetic neuropathy, abnormal and decreased sensation, usually in a stocking distribution starting at the feet but potentially in other nerves. When combined with damaged blood vessels this can lead to diabetic foot (see below). Other forms of diabetic neuropathy may present as mononeuritis or autonomic neuropathy.
- Diabetic nephropathy, damage to the kidney which can lead to chronic renal failure, eventually requiring dialysis. Diabetes mellitus is the most common cause of adult kidney failure worldwide.

Macrovascular disease

Macrovascular disease leads to cardiovascular disease, mainly by accelerating atherosclerosis:

- Coronary artery disease, leading to myocardial infarction ("heart attack") or angina
 Stroke (mainly ischemic type)
 Peripheral vascular disease, which contributes to intermittent claudication (exertion-related foot pain) as well as diabetic foot.
 Diabetic myonecrosis

Diabetic foot, often due to a combination of neuropathy and arterial disease, may cause skin ulcer and infection and, in serious cases, necrosis and gangrene. It is the most common cause of adult amputation, usually of toes and or feet, in the US and other Western countries.

Carotid artery stenosis does not occur more often in diabetes, and there appears to be a lower prevalence of abdominal aortic aneurysm. However, diabetes does cause higher morbidity, mortality and operative risks with these conditions.[14]

Treatment and management

Diabetes is a chronic disease, and emphasis is on managing short-term as well as long-term diabetes-related problems. There is an important role for patient education, nutritional support, self glucose monitoring, as well as long-term glycemic control. A scrupulous control is needed to help reduce the risk of long term complications. In addition, given the associated higher risks of cardiovascular disease, lifestyle modifications must be implemented to

control blood pressure[15] and cholesterol by exercising more, smoking cessation, and consuming an appropriate diet.

In countries with a general practitioner system, such as the United Kingdom, care may be extended mainly in the community, with hospital-based specialist input only in case of complications, difficult blood sugar control, or participation in research. In other circumstances, general practitioners and specialists may share care of a patient in a team approach. Optometrists, podiatrists/chiropodists, dietitians, physiotherapists, clinical nurse specialists (eg, Certified Diabetic Educators), or nurse practitioners may provide multidisciplinary expertise.

Nowadays, with improved diagnostic support, type-1 (insulin-dependent) diabetics can join all kinds of activities. In May 2006 for example, the Austrian mountaineer Geri Winkler became the first insulin-dependent diabetic to reach the top of Mount Everest.

Curing diabetes

The fact that type 1 diabetes is due to the failure of one of the cell types of a single organ with a relatively simple function (i.e. the failure of the islets of Langerhans) has led to the study of several possible schemes to cure diabetes.[16] In contrast, type 2 diabetes is more complex with fewer prospects of a curative measure, but further understanding of the underlying mechanism of insulin resistance may make a cure possible. Correcting insulin resistance may provide a cure for type 2 diabetes.[17]

Only those type 1 diabetics who have received a kidney-pancreas transplant (when they have developed diabetic nephropathy) and become insulin-independent may be considered "cured" from their diabetes. Still, they generally remain on long-term immunosuppressive drug and there is a possibility the autoimmune phenomenon will develop in the transplanted organ.[16]

Transplants of exogenous beta cells have been performed experimentally in both mice and humans, but this measure is not yet practical in regular clinical practice. Thus far, like any such transplant, it provokes an immune reaction and long-term immunosuppressive drug will be needed to protect the transplanted tissue.[18] An alternative technique has been proposed to place the transplanted beta cells in a semi-permeable container, isolating them from the immune system. Stem cell research has also been suggested as a potential avenue for a cure since it may permit the regrowth of islet cells which are genetically part of the treated individual, thus eliminating the need for immuno-suppressants. However, it has also been hypothesised that the same mechanism which led to islet destruction originally may simply destroy even stem-cell regenerated islets.[16]

Microscopic or nanotechnological approaches are under investigation as well, with implanted stores of insulin metered out by a rapid response valve sensitive to blood glucose levels. At least two approaches have been proposed and demonstrated in vitro. These are, in some sense, closed-loop insulin pumps.

Prevention

As little is known on the exact mechanism by which type 1 diabetes develops, there are no preventive measures available for that form of diabetes. Some studies have attributed a protective effect of breastfeeding on the development of type 1 diabetes.

Type 2 diabetes can be prevented in many cases by making changes in diet and increasing physical activity.[19] Some studies have shown delayed progression to diabetes in predisposed patients through the use of metformin[19] or valsartan.[20] Breastfeeding might also be correlated with the prevention of type 2 of the disease in mothers.[21]

As of late 2006, although there are many claims of nutritional cures, there is no reliable proof of their effectiveness. In addition, despite claims by some that vaccinations may cause diabetes, there are no studies proving any such connection.

Public health and policy

The 1989 Declaration of St Vincent was the result of international efforts to improve the care accorded to those with diabetes. Doing so is important both in terms of quality of life and life expectancy but also economically - expenses to diabetes have been shown to be a major drain on health- and productivity-related resources for healthcare systems and governments.

Several countries established more and less successful national diabetes programmes to improve treatment of the disease.[22]

Epidemiology and statistics

In 2006, according to the World Health Organization, at least 171 million people worldwide suffer from diabetes. Its incidence is increasing rapidly, and it is estimated that by the year 2030, this number will double. Diabetes mellitus occurs throughout the world, but is more common (especially type 2) in the more developed countries. The greatest increase in prevalence is, however, expected to occur in Asia and Africa, where most patients will likely be found by 2030. The increase in incidence of diabetes in developing countries follows the trend of urbanization and lifestyle changes, perhaps most importantly a "Western-style" diet. This has suggested an environmental (i.e., dietary) effect, but there is little understanding of the mechanism(s) at present, though there is much speculation, some of it most compellingly presented.

Diabetes is in the top 10, and perhaps the top 5, of the most significant diseases in the developed world, and is gaining in significance there and elsewhere.

For at least 20 years, diabetes rates in North America have been increasing substantially. In 2005 there are about 20.8 million people with diabetes in the United States alone. According to the American Diabetes Association, there are about 6.2 million people undiagnosed and about 41 million people that would be considered prediabetic.[23] However, the criteria for diagnosing diabetes in the USA means that it is more readily diagnosed than in some other countries. The Centers for Disease Control has termed the change an epidemic. The National Diabetes Information Clearinghouse estimates that

diabetes costs $132 billion in the United States alone every year. About 5%–10% of diabetes cases in North America are type 1, with the rest being type 2. The fraction of type 1 in other parts of the world differs; this is likely due to both differences in the rate of type 1 and differences in the rate of other types, most prominently type 2. Most of this difference is not currently understood.According to the American Diabetes Association, 1 in 3 Americans born after 2000 will develop diabetes in their lifetime.[24]

Alpha-glucosidase inhibitors

*Alpha-glucosidase inhibitor*s are oral anti-diabetic drugs used for diabetes mellitus type 2 that work by preventing the digestion of complex carbohydrates (such as starch). Complex carbohydrates are normally converted into simple sugars (monosaccharides) which can be absorbed through the intestine. Hence, alpha-glucosidase inhibitors reduce the impact of complex carbohydrates on blood sugar.

Examples and differences

Examples of alpha-glucosidase inhibitors include:

- Acarbose

Miglitol

Even though the drugs have a similar mechanism of action, there are subtle differences between acarbose and miglitol. Acarbose is an oligosaccharide, whereas miglitol resembles a monosaccharide. Miglitol is fairly well-absorbed by the body, as opposed to acarbose. Moreover, acarbose inhibits pancreatic alpha-amylase in addition to alpha-glucosidase.

Role in clinical use

Alpha-glucosidase inhibitors are used to establish greater glycemic control over hyperglycemia in diabetes mellitus type 2, particularly with regard to postprandial hyperglycemia. They may be used as monotherapy in conjunction with an appropriate diabetic diet and exercise, or they may be used in conjunction with other anti-diabetic drugs.

Alpha-glucosidase inhibitors may also be useful in patients with diabetes mellitus type 1; however, this use has not been officially approved by the Food and Drug Administration.

Mechanism of action

Alpha-glucosidase inhibitors are saccharides that act as competitive inhibitors of enzymes needed to digest carbohydrates: specifically alpha-glucosidase enzymes in the brush border of the small intestines. The membrane-bound intestinal alpha-glucosidases hydrolyze oligosaccharides, trisaccharides, and disaccharides to glucose and other monosaccharides in the small intestine.

Acarbose also blocks pancreatic alpha-amylase in addition to inhibiting membrane-bound alpha-glucosidases. Pancreatic alpha-amylase hydrolyzes complex starches to oligosaccharides in the lumen of the small intestine.

Inhibition of these enzyme systems reduces the rate of digestion of complex carbohydrates. Less glucose is absorbed because the carbohydrates are not broken down into glucose molecules. In diabetic patients, the short-term effect of these drugs therapies is to decrease current blood glucose levels: the long term effect is a small reduction in hemoglobin A1c level. (From Drug Therapy in Nursing, 2nd ed)

Dosing

Since alpha-glucosidase inhibitors are competitive inhibitors of the digestive enzymes, they must be taken at the start of main meals to have maximal effect. Their effects on blood sugar levels following meals will depend on the amount of complex carbohydrates in the meal.

Side effects & precautions

Since alpha-glucosidase inhibitors prevent the degradation of complex carbohydrates into glucose, the carbohydrates will remain in the intestine. In the colon, bacteria will digest the complex carbohydrates, thereby causing gastrointestinal side effects such as flatulence

and diarrhea. Since these effects are dose-related, it is generally advised to start with a low dose and gradually increase the dose to the desired amount.

If a patient using an alpha-glucosidase inhibitor suffers from a bout of hypoglycemia, the patient should eat something containing monosaccharides, such as glucose tablets. Since the drug will prevent the digestion of complex carbohydrates, starchy foods may not effectively reverse a hypoglycemic episode in a patient taking an alpha-glucosidase inhibitor.

Dipeptidyl peptidase-4 inhibitors

Dipeptidyl peptidase 4 inhibitors, also *DPP-4 inhibitors*, are a new class of oral hypoglycemics. Their mechanism of action is thought to result from increased GLP-1,[1][2] which inhibits glucagon release (which increases the blood glucose).

Drugs belonging to this class are vildagliptin and sitagliptin.

Insulin therapies

Insulin crystals

Other names: *insulin*

Genetic data

Locus: Chr. 11 p15.5

Gene code: HUGO code:INS

Gene type: Protein coding

Protein Structure/Function

Molecular Weight: 11982 (Da)

Structure: Solution Structure of Human pro-Insulin Polypeptide

Protein type: insulin family

Functions: glucose regulation

Domains: INS domain

Motifs: SP motif

Other

Taxa expressing: Homo sapiens; homologs: in metazoan taxa from invertebrates to mammals

Cell types: pancreas: beta cells of the Islets of Langerhans

Subcellular localization: extracellular fluids

Covalent modifications: glycation, proteolytic cleavage

Pathway(s): Insulin signaling pathway (KEGG); Type II diabetes mellitus (KEGG); Type I diabetes mellitus (KEGG); Maturity onset diabetes of the young (KEGG); Regulation of actin cytoskeleton (KEGG)

Receptor/Ligand data

Antagonists: glucagon, steroids, most stress hormomes

Medical/Biotechnological data

Diseases: familial hyperproinsulinemia, Diabetes mellitus

Pharmaceuticals: insulin (Humulin Novolin), insulin lispro (Humalog), insulin aspart (Novolog), insulin detemir (Levemir), insulin glargine (Lantus), etc

Insulin (from Latin insula, "island", as it is produced in the Islets of Langerhans in the pancreas) is a polypeptide hormone that regulates carbohydrate metabolism. Apart from being the primary effector in carbohydrate homeostasis, it has effects on fat metabolism and it can change the liver's ability to release fat stores. Insulin's concentration has extremely widespread effects throughout the body.

Insulin is used medically in some forms of diabetes mellitus. Patients with type 1 diabetes mellitus depend on exogenous insulin (commonly injected subcutaneously) for their survival because of an absolute deficiency of the hormone; patients with type 2 diabetes mellitus have either relatively low insulin production or insulin resistance or both, and a non-trivial fraction of type 2 diabetics eventually require insulin administration when other medications become inadequate in controlling blood glucose levels.

Insulin has a molecular weight of 5808 Da. It has the molecular formula $C_{257}H_{383}N_{65}O_{77}S_{6}$.

Insulin structure varies slightly between species of animal. Its carbohydrate metabolism regulatory function strength in humans also varies. Porcine (pig) insulin is particularly close to humans'.

Discovery and characterization

In 1869 Paul Langerhans, a medical student in Berlin, was studying the structure of the pancreas under a microscope when he noticed some previously-unidentified cells scattered in the exocrine tissue. The function of the "little heaps of cells," later known as the Islets of Langerhans, was unknown, but Edouard Laguesse later argued that they may produce a secretion that plays a regulatory role in digestion.

In 1889, the Polish-German physician Oscar Minkowski in collaboration with Joseph von Mehring removed the pancreas from a healthy dog to demonstrate this assumed role in digestion. Several days after the dog's pancreas was removed, Minkowski's animal keeper noticed a swarm of flies feeding on the dog's urine. On testing the urine they found that there was sugar in the dog's urine, demonstrating for the first time the relationship between the pancreas and diabetes. In 1901, another major step was taken by Eugene Opie, when he clearly established the link between the Islets of Langerhans and diabetes: Diabetes mellitus.... is caused by destruction of the islets of Langerhans and occurs only when these bodies are in part or wholly destroyed. Before this demonstration, the link between the pancreas and diabetes was clear, but not the specific role of the islets.

Over the next two decades, several attempts were made to isolate the secretion of the islets as a potential treatment. In 1906 George Ludwig Zuelzer was partially successful treating dogs with pancreatic extract, but was unable to continue his work. Between 1911 and 1912, E.L. Scott at the University of Chicago used aqueous pancreatic extracts and noted a slight diminution of glycosuria, but was unable to convince his director and the research was shut down. Israel Kleiner demonstrated similar effects at Rockefeller University in 1919, but his work was interrupted by World War I and he was unable to return to it. Nicolae Paulescu, a professor of physiology at the Romanian School of Medicine, published similar work in 1921 that was carried out in France and patented in Romania, and it has been argued ever since that he is the rightful discoverer.

However, the Nobel prizes committee in 1923 credited the practical extraction of insulin to a team at the University of Toronto. In October 1920, Frederick Banting was reading one of Minkowski's papers and concluded that it is the very digestive secretions that Minkowski had originally studied that were breaking down the secretion, thereby making it impossible to extract successfully. He jotted a note to himself Ligate pancreatic ducts of the dog. Keep dogs alive till acini degenerate leaving islets. Try to isolate internal secretion of these and relieve glycosurea.

He travelled to Toronto to meet with J.J.R. Macleod, who was not entirely impressed with his idea. Nevertheless, he supplied Banting with a lab at the University, an assistant, medical student Charles Best, and ten dogs, while he left on vacation during the summer of 1921. Their method was tying a ligature (string) around the pancreatic duct, and, when examined several weeks later, the pancreatic digestive cells had died and been absorbed by the immune system, leaving thousands of islets. They then isolated the protein from these islets to produce what they called isletin. Banting and Best were then able to keep a pancreatectomized dog alive all summer.

Macleod saw the value of the research on his return from Europe, but demanded a re-run to prove the method actually worked. Several weeks later it was clear the second run was

also a success, and he helped publish their results privately in Toronto that November. However, they needed six weeks to extract the isletin, dramatically slowing testing. Banting suggested that they try to use fetal calf pancreas, which had not yet developed digestive glands; he was relieved to find that this method worked well. With the supply problem solved, the next major effort was to purify the protein. In December 1921, Macleod invited the biochemist James Collip to help with this task, and, within a month, he felt ready to test.

On January 11, 1922, Leonard Thompson, a fourteen-year-old diabetic, was given the first injection of insulin. However, the extract was so impure that he suffered a severe allergic reaction, and further injections were canceled. Over the next 12 days, Collip worked day and night to improve the extract, and a second dose injected on the 23rd. This was completely successful, not only in not having obvious side-effects, but in completely eliminating the symptoms of diabetes. However, Banting and Best never worked well with Collip, regarding him as something of an interloper, and Collip left soon after.

Over the spring of 1922, Best managed to improve his techniques to the point where large quantities of insulin could be extracted on demand, but the extract remained impure. However, they had been approached by Eli Lilly and Company with an offer of help shortly after their first publications in 1921, and they took Lilly up on the offer in April. In November, Lilly made a major breakthrough, and were able to produce large quantities of pure insulin. Insulin was offered for sale shortly thereafter.

Nobel Prizes

- Macleod and Banting were awarded the Nobel Prize in Physiology or Medicine in 1923 for the discovery of insulin. Banting, insulted that Best was not mentioned, shared his prize with Best, and MacLeod immediately shared his with Collip. The patent for insulin was sold to the University of Toronto for one dollar.
- The exact sequence of amino acids comprising the insulin molecule, the so-called primary structure, was determined by British molecular biologist Frederick Sanger. It was the first protein to have its structure be completely determined. He was awarded the Nobel Prize in Chemistry in 1958.
- In 1967, after decades of work, Dorothy Crowfoot Hodgkin determined the spatial conformation of the molecule, by means of X-ray diffraction studies. She had been awarded a Nobel Prize in Chemistry in 1964 for the development of crystallography.
- Rosalyn Sussman Yalow received the 1977 Nobel Prize in Medicine for the development of the radioimmunoassay for insulin.

Structure and production

Insulin is synthesized in humans, and other mammals, within the beta cells (^{2}-cells) of the islets of Langerhans in the pancreas. One to three million islets of Langerhans (pancreatic islets) form the endocrine part of the pancreas, which is primarily an exocrine gland. The endocrine part accounts for only 2% of the total mass of the pancreas. Within the islets of Langerhans, beta cells constitute 60–80% of all the cells.

In beta cells, insulin is synthesized from the proinsulin precursor molecule by the action of proteolytic enzymes known as prohormone convertases (PC1 and PC2), as well as the exoprotease carboxypeptidase E. These modifications of proinsulin remove the center portion of the molecule, or C-peptide, from the C- and N- terminal ends of the proinsulin. The remaining polypeptides (51 amino acids in total), the B- and A- chains, are bound together by disulfide bonds. Confusingly, the primary sequence of proinsulin goes in the order "B-C-A", since B and A chains were identified on the basis of mass, and the C peptide was discovered after the others.

Amongst vertebrates, insulin has been highly conserved. Bovine insulin differs from human insulin in only three amino acid residues, and porcine insulin in one residue. Even insulin from some species of fish is also close enough to human insulin to be effective in humans.

Actions on cellular and metabolic level

The actions of insulin on the global human metabolism level include:

- Control of cellular intake of certain substances, most prominently glucose in muscle and adipose tissue (about T of body cells).
- Increase of DNA replication and protein synthesis via control of amino acid uptake.
- Modification of the activity of numerous enzymes (allosteric effect).

The actions of insulin on cells include:

- Increased glycogen synthesis – insulin forces storage of glucose in liver (and muscle) cells in the form of glycogen; lowered levels of insulin cause liver cells to convert glycogen to glucose and excrete it into the blood. This is the clinical action of insulin which is directly useful in reducing high blood glucose levels as in diabetes.
- Increased fatty acid synthesis – insulin forces fat cells to take in blood lipids which are converted to triglycerides; lack of insulin causes the reverse.
- Increased esterification of fatty acids – forces adipose tissue to make fats (ie, triglycerides) from fatty acid esters; lack of insulin causes the reverse.
- Decreased proteinolysis – forces reduction of protein degradation; lack of insulin increases protein degradation.
- Decreased lipolysis – forces reduction in conversion of fat cell lipid stores into blood fatty acids; lack of insulin causes the reverse.
- Decreased gluconeogenesis – decreases production of glucose from various substrates in liver; lack of insulin causes glucose production from assorted substrates in the liver and elsewhere.
- Increased amino acid uptake – forces cells to absorb circulating amino acids; lack of insulin inhibits absorption.
- Increased potassium uptake – forces cells to absorb serum potassium; lack of insulin inhibits absorption.

- Arterial muscle tone – forces arterial wall muscle to relax, increasing blood flow, especially in micro arteries; lack of insulin reduces flow by allowing these muscles to contract.

Regulatory action on blood glucose

Despite long intervals between meals or the occasional consumption of meals with a substantial carbohydrate load (e.g., half a birthday cake or a bag of potato chips), human blood glucose levels normally remain within a narrow range. In most humans this varies from about 70 mg/dl to perhaps 110 mg/dl (3.9 to 6.1 mmol/litre) except shortly after eating when the blood glucose level rises temporarily. This homeostatic effect is the result of many factors, of which hormone regulation is the most important.

It is usually a surprise to realize how little glucose is actually maintained in the blood, and body fluids. The control mechanism works on very small quantities. In a healthy adult male of 75 kg with a blood volume of 5 litres, a blood glucose level of 100 mg/dl or 5.5 mmol/l corresponds to about 5 g (1/5 ounce) of glucose in the blood and approximately 45 g (1½ ounces) in the total body water (which obviously includes more than merely blood and will be usually about 60% of the total body weight in men). A more familiar comparison may help -- 5 grams of glucose is about equivalent to a commercial sugar packet (as provided in many restaurants with coffee or tea).

There are two types of mutually antagonistic metabolic hormones affecting blood glucose levels:

- catabolic hormones (such as glucagon, growth hormone, and catecholamines), which increase blood glucose
- and one anabolic hormone (insulin), which decreases blood glucose

Mechanisms which restore satisfactory blood glucose levels after hypoglycemia must be quick, and effective, because of the immediate serious consequences of insufficient glucose (in the extreme, coma, less immediately dangerously, confusion or unsteadiness, amongst many other effects). This is because, at least in the short term, it is far more dangerous to have too little glucose in the blood than too much. In healthy individuals these mechanisms are indeed generally efficient, and symptomatic hypoglycemia is generally only found in diabetics using insulin or other pharmacologic treatment. Such hypoglycemic episodes vary greatly between persons and from time to time, both in severity and swiftness of onset. In severe cases prompt medical assistance is essential, as damage (to brain and other tissues) and even death will result from sufficiently low blood glucose levels.

Beta cells in the islets of Langerhans are sensitive to variations in blood glucose levels through the following mechanism (see figure to the right):

- Glucose enters the beta cells through the glucose transporter GLUT2
- Glucose goes into the glycolysis and the respiratory cycle where multiple high-energy ATP molecules are produced by oxidation
- Dependent on blood glucose levels and hence ATP levels, the ATP controlled potassium channels (K^+) close and the cell membranes depolarize
- On depolarisation, voltage controlled calcium channels (Ca^{2+}) open and calcium flows into the cells

- An increased calcium level causes activation of phospholipase C, which cleaves the membrane phospholipid phosphatidyl inositol 4,5-bisphosphate into inositol 1,4,5-triphosphate and diacylglycerol.
- Inositol 1,4,5-triphosphate (IP3) binds to receptor proteins in the membrane of endoplasmic reticulum (ER). This allows the release of Ca**2+** from the ER via IP3 gated channels, and further raises the cell concentration of calcium.
- Significantly increased amounts of calcium in the cells causes release of previously synthesised insulin, which has been stored in secretory vesicles
- The calcium level also regulates expression of the insulin gene via the calcium responsive element binding protein (CREB).

This is the main mechanism for release of insulin and regulation of insulin synthesis. In addition some insulin synthesis and release takes place generally at food intake, not just glucose or carbohydrate intake, and the beta cells are also somewhat influenced by the autonomic nervous system. The signalling mechanisms controlling this are not fully understood.

Other substances known which stimulate insulin release are acetylcholine, released from vagus nerve endings (parasympathetic nervous system), cholecystokinin, released by enteroendocrine cells of intestinal mucosa and gastrointestinal inhibitory peptide (GIP). The first of these act similarly as glucose through phospholipase C, while the last acts through the mechanism of adenylate cyclase.

The sympathetic nervous system (via ±2-adrenergic agonists such as norepinephrine) inhibits the release of insulin.

When the glucose level comes down to the usual physiologic value, insulin release from the beta cells slows or stops. If blood glucose levels drop lower than this, especially to dangerously low levels, release of hyperglycemic hormones (most prominently glucagon from Islet of Langerhans' alpha cells) forces release of glucose into the blood from cellular stores, primarily liver cell stores of glycogen. Release of insulin is strongly inhibited by the stress hormone norepinephrine (noradrenaline), which leads to increased blood glucose levels during stress.

Signal transduction

There are special transporter proteins in cell membranes through which glucose from the blood can enter a cell. These transporters are, indirectly, under insulin control in certain body cell types (eg, muscle cells). Low levels of circulating insulin, or its absence, will prevent glucose from entering those cells (eg, in untreated Type 1 diabetes). However, more commonly there is a decrease in the sensitivity of cells to insulin (eg, the reduced insulin sensitivity characteristic of Type 2 diabetes), resulting in decreased glucose absorption. In either case, there is 'cell starvation', weight loss, sometimes extreme. In a few cases, there is a defect in the release of insulin from the pancreas. Either way, the effect is, characteristically, the same: elevated blood glucose levels.

Activation of insulin receptors leads to internal cellular mechanisms which directly affect glucose uptake by regulating the number and operation of protein molecules in the cell membrane which transport glucose into the cell. The genes which specify the proteins which

make up the insulin receptor in cell membranes have been identified and the structure of the interior, cell membrane section, and now, finally after more than a decade, the extra-membrane structure of receptor (Australian researchers announced the work 2Q 2006).

Two types of tissues are most strongly influenced by insulin, as far as the stimulation of glucose uptake is concerned: muscle cells (myocytes) and fat cells (adipocytes). The former are important because of their central role in movement, breathing, circulation, etc, and the latter because they accumulate excess food energy against future needs. Together, they account for about T of all cells in a typical human body.

Hypoglycemia

Although other cells can use other fuels for a while (most prominently fatty acids), neurons depend on glucose as a source of energy in the non-starving human. They do not require insulin to absorb glucose, unlike muscle and adipose tissue, and they have very small internal stores of glycogen. Glycogen stored in liver cells (unlike glycogen stored in muscle cells) can be converted to glucose, and released into the blood, when glucose from digestion is low or absent, and the glycerol backbone in triglycerides can also be used to produce blood glucose. Exhaustion of these sources can, either temporarily or on a sustained basis, if reducing blood glucose to a sufficiently low level, first and most dramatically manifest itself in impaired functioning of the central nervous system – dizziness, speech problems, even loss of consciousness, are not unknown. This is known as hypoglycemia or, in cases producing unconsciousness, "hypoglycemic coma" (formerly termed "insulin shock" from the most common causative agent). Endogenous causes of insulin excess (such as an insulinoma) are very rare, and the overwhelming majority of hypoglycemia cases are caused by human action (e.g. iatrogenic, caused by medicine), and are usually accidental. There have been a few reported cases of murder, attempted murder or suicide using insulin overdoses, but most insulin shocks appear to be due to mismanagement of insulin (didn't eat as much as anticipated, or exercised more than expected), or a mistake (e.g. 20 units of insulin instead of 2).hhhh

Possible causes of hypoglycemia include:

- Oral hypoglycemic agents (e.g., any of the sulfonylureas, or similar drugs, which increase insulin release from beta cells in response to a particular blood glucose level).
- External insulin (usually injected subcutaneously).
- Ingestion of low-carbohydrate sugar substitutes (animal studies show these can trigger insulin release according to a report in Discover magazine August 2005, p18).

Diseases and syndromes

There are several conditions in which insulin disturbance is pathologic:

- Diabetes mellitus – general term referring to all states characterized by hyperglycemia.

  - Type 1 – autoimmune-mediated destruction of insulin producing beta cells in the pancreas resulting in absolute insulin deficiency.
  - Type 2 – multifactoral syndrome with combined influence of genetic susceptibility and influence of environmental factors, the best known being obesity, age, and physical inactivity, resulting in insulin resistance in cells requiring insulin for glucose absorption. This form of diabetes is strongly inherited.
  - Other types of impaired glucose tolerance (see the diabetes article).
- Insulinoma or reactive hypoglycemia.
- Metabolic syndrome – a precondition first called Metabolic Syndrome X by Gerald Reaven, and sometimes called prediabetes. It is characterized by elevated blood pressure, dyslipidemia (disturbances in blood cholesterol forms and other blood lipids), and increased waist circumference (at least in populations in much of the developed world). The basic underlying cause is insulin resistance, a diminished capacity for insulin response in some tissues (eg, muscle, fat, liver) to respond to insulin. Untreated, Metabolic Syndrome can lead to morbidities such as essential hypertension, obesity, Type 2 diabetes, and cardiovascular disease (CVD).
- Polycystic ovary syndrome – a complex syndrome in women in the reproductive years where there is anovulation and androgen excess commonly displayed as hirsutism. In many cases of PCOS insulin resistance is present.

As a medication

Principles

Insulin is absolutely required for all animal (including human) life. The mechanism is almost identical in nematode worms (e.g. C. elegans), fish, and in mammals. In humans, insulin deprivation due to the removal or destruction of the pancreas leads to death in days or at most weeks. Insulin must be administered to patients in whom there is a lack of the hormone for this, or any other, reason. Clinically, this is called diabetes mellitus type 1.

The initial source of insulin for clinical use in humans was from cow, horse, pig or fish pancreases. Insulin from these sources is effective in humans as it is nearly identical to human insulin (three amino acid difference for bovine insulin, one amino acid difference for porcine). Insulin is obviously a protein which has been very strongly conserved across evolutionary time. Differences in suitability of beef, pork, or fish insulin preparations for particular patients have been primarily the result of preparation purity and of allergic reactions to assorted non-insulin substances remaining in those preparations. Purity has improved more or less steadily since the 1920s, but allergic reactions have continued though slowly reducing in severity. Insulin production from animal pancreases was widespread for decades, but there are very few patients today relying on insulin from these sources.

Human insulin is now manufactured for widespread clinical use using genetic engineering techniques, which significantly reduces impurity reaction problems. Eli Lilly marketed the first such insulin, Humulin, in 1982. Humulin was the first medication

produced using modern genetic engineering techniques, in which actual human DNA is inserted into a host cell (E. coli in this case). The host cells are then allowed to grow and reproduce normally, and due to the inserted human DNA, they produce actual human insulin.

Genentech developed the technique Lilly used to produce Humulin. Novo Nordisk has also developed a genetically engineered insulin independently. Most insulins used clinically are produced this way, for they avoid most of the allergic reaction problem.

Since January 2006, all insulins distributed in the U.S. and some other countries are human insulins or their analogs. A special FDA importation process is required to obtain beef or pork insulin for use in the U.S., though there may be some remaining stocks of pork insulin made by Lilly in 2005 or earlier.

Modes of administration

Unlike many medicines, insulin cannot be taken orally; like other proteins in the gastrointestinal tract, it is reduced to its amino acid components, whereupon all 'insulin activity' is lost. There is research underway to develop methods of protecting insulin so that it can be taken orally, but none has yet reached clinical use (see oral insulin). Instead insulin is usually taken as subcutaneous injections by single-use syringes with needles, an insulin pump or by repeated-use insulin pens with needles.

There are several problems with insulin as a clinical treatment for diabetes:

- Mode of administration.
- Selecting the 'right' dose and timing.
- Selecting an appropriate insulin preparation (typically on 'speed of onset and duration of action' grounds).
- Adjusting dosage and timing to fit food amounts and types.
- Adjusting dosage and timing to fit exercise undertaken.
- Adjusting dosage, type, and timing to fit other conditions as for instance the increased stress of illness.
- The dosage is non-physiological in that a subcutaneous bolus dose of insulin alone is administered instead of combination of insulin and C-peptide being released gradually and directly into the portal vein.
- It is simply a nuisance for patients to inject themselves once or several times a day.
- It may be dangerous in the case of mistake (most especially 'too much' insulin).

There have been attempts to improve upon this mode of administering insulin, as many people find injection awkward and painful. One alternative is jet injection (also sometimes used for vaccinations), which has different insulin delivery peaks and durations as compared to needle injection. Some diabetics find control possible with jet injectors, but not with hypodermic injection. There are also 'insulin pumps' of various types which are 'electrical injectors' attached to a semi-permanently implanted needle (i.e. a catheter). Some who cannot achieve adequate glucose control by conventional injection (or sometimes jet injection) are able to do so with the appropriate pump.

An insulin pump is a reasonable solution for some. However there are limitations - cost, the potential for hypoglycemic episodes, catheter problems, and, so far, no approvable means of controlling insulin delivery in the field based on current blood glucose levels. If too much insulin is delivered, or the patient eats less than normal, there will be hypoglycemia. On the other hand, if too little insulin is delivered, there will be hyperglycemia. Both of these can lead to life-threatening conditions. In addition, indwelling catheters pose the risk of infection and ulceration. However, that risk can be minimized by keeping catheter sites clean. Thus far, insulin pumps require care and effort to use correctly. However, some diabetics are able to keep their glucose in reasonable control only on a pump.

Researchers have produced a watch-like device that tests for blood glucose levels through the skin and administers corrective doses of insulin through pores in the skin. Both electricity and ultrasound have been found to make the skin temporarily porous. The insulin administration aspect remains experimental, but the blood glucose test aspect of 'wrist appliances' is commercially available.

Another 'improvement' would be to avoid periodic insulin administration by a self-regulating insulin source, for instance, pancreatic, or beta cell, transplantation. Transplantation of an entire pancreas (as an individual organ) is difficult, and is not common. Generally, it is performed in conjunction with liver or kidney transplant. However, transplantation of only pancreatic beta cells is a possibility. It has been highly experimental (for which read 'prone to failure') for many years, but some researchers in Alberta, Canada, have developed techniques with a high initial success rate (about 90% in one group). Beta cell transplant may become practical and common in the near future. Additionally, some researchers have explored the possibility of transplanting genetically engineered non-beta cells to secrete insulin.[1] Clinically testable results are far from realization. Several other non-transplant methods of automatic insulin delivery are being developed in research labs, but none is close to clinical approval.

Inhaled insulin is under investigation, as are several other insulin administration techniques. Currently the only inhalable insulin approved by the Food and Drug Administration [1]is Exubera. Inhaled insulin has been shown to have similar efficacy to injected insulin, both in terms of controlling glucose levels and blood half-life. When patients were switched from injected to inhaled insulin, no significant difference was found in HBA1c levels over three months. Patients showed no significant weight gain or pulmonary function over the length of the trial, when compared to the baseline.[2] However following its commercial launch in 2005 into the UK, it has not (as of July 2006) been recommended by National Institute for Health and Clinical Excellence for routine use, except in cases where there is "proven injection phobia diagnosed by a psychiatrist or psychologist".[3]

An additional method of administration of insulin to diabetics is pulsatile insulin. In this method insulin is pulsed into the patient, mimicking the physiological secretions of insulin by the pancreas.

Dosage and timing

The central problem for those requiring external insulin is picking the right dose of insulin and the right timing.

Physiological regulation of blood glucose, as in the non-diabetic, would be best. Increased blood glucose levels after a meal is a stimulus for prompt release of insulin from the pancreas. The increased insulin level causes glucose absorption and storage in cells, reducing glycogen to glucose conversion, reducing blood glucose levels, and so reducing insulin release. The result is that the blood glucose level rises somewhat after eating, and within an hour or so returns to the normal 'fasting' level. Even the best diabetic treatment with human insulin, however administered, falls short of normal glucose control in the non-diabetic.

Complicating matters is that the composition of the food eaten (see glycemic index) affects intestinal absorption rates. Glucose from some foods is absorbed more (or less) rapidly than the same amount of glucose in other foods. And, fats and proteins both cause delays in absorption of glucose from carbohydrate eaten at the same time. As well, exercise reduces the need for insulin even when all other factors remain the same, since working muscle has some ability to take up glucose without the help of insulin.

It is, in principle, impossible to know for certain how much insulin (and which type) is needed to 'cover' a particular meal in order to achieve a reasonable blood glucose level within an hour or two after eating. Non-diabetics' beta cells routinely and automatically manage this by continual glucose level monitoring and insulin release. All such decisions by a diabetic must be based on experience and training (ie, at the direction of a physician or PA, or in some places a specialist diabetic educator) and, further, specifically based on the individual experience of the patient. It is not straightforward and should never be done by habit or routine, but with care can be done quite successfully in practice.

For example, some diabetics require more insulin after drinking skim milk than they do after taking an equivalent amount of fat, protein, carbohydrate, and fluid in some other form. Their particular reaction to skimmed milk is different from other diabetics', but the same amount of whole milk is likely to cause a still different reaction even in that person. Whole milk contains considerable fat while skimmed milk has much less. It is a continual balancing act for all diabetics, especially for those taking insulin.

Insulin dependent diabetics require a base level of insulin (Basal Insulin), as well as extra short acting insulin to cope with meals (Bolus Insulin). Maintaining the basal rate and the bolus rate is a continuous balancing act that all insulin diabetics have to manage each day. This is normally achieved through regular blood tests, although there is work being undertaken on continuous blood sugar testing equipment.

It is important to notice that diabetics generally need more insulin than the usual -- not less -- during physical stress like infections or surgeries.

Types

Medical preparations of insulin (from the major suppliers — Eli Lilly and Novo Nordisk — or from any other) are never just 'insulin in water'. Clinical insulins are specially prepared mixtures of insulin plus other substances. These delay absorption of the insulin, adjust the pH of the solution to reduce reactions at the injection site, and so on.

The insulin molecules in an insulin analog is slightly modified so that they are:

- Absorbed rapidly enough to mimic real beta cell insulin (Lilly's is lispro, Novo Nordisk's is aspart).

- Steadily absorbed after injection instead of having a 'peak' followed by a more or less rapid decline in insulin action (Novo Nordisk' version is Insulin detemir and Aventis' version is Insulin glargine).
- All while retaining insulin action in the human body.

The management of choosing insulin type and dosage / timing should be done by an experienced medical professional working with the diabetic.

Allowing blood glucose levels to rise, though not to levels which cause acute hyperglycemic symptoms, is not a sensible choice. Several large, well designed, long term studies have conclusively shown that diabetic complications decrease markedly, linearly, and consistently as blood glucose levels approach 'normal' patterns over long periods. In short, if a diabetic closely controls blood glucose levels (ie, on average, both over days and weeks, and avoiding too high peaks after meals) the rate of diabetic complications goes down. If glucose levels are very closely controlled, that rate can even approach 'normal'. The chronic diabetic complications include cerebrovascular accidents (CVA or stroke), heart attack, blindness (from proliferative diabetic retinopathy), other vascular damage, nerve damage from diabetic neuropathy, or kidney failure from diabetic nephropathy. These studies have demonstrated beyond doubt that, if it is possible for a patient, so-called intensive insulinotherapy is superior to conventional insulinotherapy. However, close control of blood glucose levels (as in intensive insulinotherapy) does require care and considerable effort, for hypoglycemia is dangerous and can be fatal.

A good measure of long term diabetic control (over approximately 90 days in most people) is the serum level of glycosylated hemoglobin (HbA1c). A shorter term integrated measure (over two weeks or so) is the so-called fructosamine level, which is a measure of similarly glyclosylated proteins (chiefly albumin) with a shorter half life in the blood. There is a commercial meter available which measures this level in the field.

The commonly used types of insulin are:

- Quick-acting, such as insulin lispro -- begins to work within 5 to 15 minutes and is active for 3 to 4 hours.
- Short-acting, such as regular insulin -- starts working within 30 minutes and is active about 5 to 8 hours.
- Intermediate-acting, such as NPH, or lente insulin -- starts working in 1 to 3 hours and is active 16 to 24 hours.
- Long-acting, such as ultralente insulin -- starts working in 4 to 6 hours, and is active 24 to 28 hours, and Insulin glargine or Insulin detemir -- both start working within 1 to 2 hours and continue to be active, without peaks or dips, for about 24 hours.
- A mixture of NPH and regular insulin -- starts working in 30 minutes and is active 16 to 24 hours. There are several variations with different proportions of the mixed insulins.

Abuse

There are reports that some patients abuse insulin by injecting larger doses that lead to mild hypoglycemic states. This is extremely dangerous. Severe acute or prolonged hypoglycemia can result in brain damage or death.

On July 23, 2004, news reports claim that a former spouse of a prominent international track athlete said that, among other drugs, the ex-spouse had used insulin as a way of 'energizing' the body. The intended implication would seem to be that insulin has effects similar to those alleged for some steroids. This is not so; eighty years of insulin use has given no reason to believe it to be in any respect a performance enhancer for non diabetics. Improperly treated diabetics are, to be sure, more prone than others to exhaustion and tiredness, and in some of these cases, proper administration of insulin can relieve such symptoms. However, insulin is not, chemically or clinically, a steroid, and its use in non diabetics is dangerous and always an abuse outside of a well-equipped medical facility.

"Game of Shadows," by reporters Mark Fainaru-Wada and Lance Williams, includes allegations that San Francisco Giant, Barry Bonds, used insulin in the apparent belief that it would increase the effectiveness of the growth hormone he was (also alleged to be) taking. On top of this, non-prescribed insulin is a banned drug at the Olympics and other global competitions.

Timeline

- 1922 Banting and Best use bovine insulin extract in human

1923 Eli Lilly produces commercial quantities of bovine insulin
1923 Hagedorn founds the Nordisk Insulinlaboratorium in Denmark -- forerunner of Novo Nordisk
1926 Nordisk receives a Danish charter to produce insulin as a non profit
1936 Canadians D.M. Scott, A.M. Fisher formulate a zinc insulin mixture and license to Novo
1936 Hagedorn discovers that adding protamine to insulin prolongs the effect of insulin
1946 Nordisk formulates Isophane® porcine insulin aka Neutral Protamine Hagedorn or NPH insulin
1946 Nordisk crystallizes a protamine and insulin mixture
1950 Nordisk markets NPH insulin
1953 Novo formulates Lente® porcine and bovine insulins by adding zinc for longer lasting insulin
1973 Purified monocomponent (MC) insulin is introduced
1978 Genentech produces human insulin in Escheria coli bacteria using recombinant DNA
1981 Novo Nordisk chemically and enzymatically converts bovine to human insulin
1982 Genentech human insulin (above) approved
1983 Eli Lilly produces recombinant human insulin, Humulin®
1985 Axel Ullrich sequences the human insulin receptor
1988 Novo Nordisk produces recombinant human insulin
1996 Lilly Humalog® "lyspro" insulin analogue approved

2004 Aventis Lantus® "glargine" insulin analogue approved for clinical use [citation needed]
2006 Novo Nordisk Levemir® "detemir" approved for clincal use in the US.

Meglitinides

The *meglitinide* class of drugs treat diabetes type 2 by blocking the potassium channels in beta cells, which closes the ATP-dependent potassium channels and opens the cells' calcium channels. The resulting calcium influx causes the cells to secrete insulin.

Drugs

The main branded drug in the meglitinide class is Novo Nordisk's Prandin(repaglinide), which gained FDA approval in 1997. Another type of drug in this class is nateglinide (Starlix)

These drugs should be taken 0-30 minutes prior to eating. Follow the instructions given to you by your physician/nurse.

Side-effects

Side effects include weight gain and hypoglycemia. While the potential for hypoglycemia is less than for those on sulfonylureas, it is still a serious potential side effect that can be life-threatening. Patients on this medication should know the signs and symptoms of hypoglycemia and appropriate action to take.

Sulfonylureas

Sulfonylurea derivatives are a class of antidiabetic drugs that are used in the management of diabetes mellitus type 2 ("adult-onset"). They act by increasing insulin release from the beta cells in the pancreas.

Drugs in this class

First generation:

- Chlorpropamide
- Tolbutamide
- Tolazamide

Second generation:

- Glipizide
- Gliclazide
- Glibenclamide (glyburide)
- Glimepiride
- Gliquidone

Chemistry

Please see individual members of the class for their chemical structure

All sulfonylureas have a central phenyl ring with two branching chains

Pharmacology

Method of action

Sulfonylureas bind to an ATP-dependent K+ channel on the cell membrane of pancreatic beta cells. This inhibits a tonic, hyperpolarizing outflux of potassium, which causes the electric potential over the membrane to become more positive. This depolarization opens voltage-gated Ca**2+** channels. The rise in intracellular calcium leads to increased fusion of insulin granulae with the cell membrane, and therefore increased secretion of (pro)insulin.

There is some evidence that sulfonylureas also sensitize ²-cells to glucose, that they limit glucose production in the liver, that they decrease lipolysis (breakdown and release of fatty acids by adipose tissue) and decrease clearance of insulin by the liver.

Pharmacokinetics

Various sulfonylureas have different pharmacokinetics. The choice depends on the propensity of the patient to develop hypoglycemia - long-acting sulfonylureas with active metabolites can induce hypoglycemia. They can, however, help achieve glycemic control when tolerated by the patient. The shorter-acting agents may not control blood sugar levels adequately.

Due to varying half-life, some drugs have to be taken twice (e.g. tolbutamide) or three times a day rather than once (e.g. glimepiride). The short-acting agents may have to be taken about 30 minutes before the meal, to ascertain maximum efficacy when the food leads to increased blood glucose levels.

Some sulfonylureas are metabolised by liver metabolic enzymes (cytochrome P450) and inducers of this enzyme system (such as the antibiotic rifampicin) can therefore increase the clearance of sulfonylureas. In addition, because some sulfonylureas are bound to plasma proteins, use of drugs that also bind to plasma proteins can release the sulfonylureas from their binding places, leading to increased clearance.

Uses

Sulfonylureas are used almost exclusively in diabetes mellitus type 2. Other types of diabetes generally do not respond to sulfonylurea therapy, or (in diabetes of pregnancy) there are other contraindications.

Although for many years sulfonylureas were the first drugs to be used in new cases of diabetes, in the 1990s it was discovered that obese patients might benefit more from metformin.

In about 10% of patients, sulfonylureas alone are ineffective in controlling blood glucose levels. Addition of metformin or a thiazolidinedione may be necessary, or (ultimately) insulin. Triple therapy of sulfonylureas, a biguanide (metformin) and a thiazolidinedione is generally discouraged, but some doctors prefer this combination over resorting to insulin.

Side-effects and cautions

Sulfonylureas, as opposed to metformin and the thiazolidinediones, can induce hypoglycemia when insulin production overshoots. It is treated with sugary food, or (in the

case of hypoglycemic coma) with intravenous dextrose. The best way to prevent this side-effect is to choose the lowest possible dose that adequately controls glucose levels.

Like insulin, sulfonylureas can induce weight gain, mainly as a result of fluid retention and improvement of osmotic diuresis. Other side-effects are: abdominal upset, headache and hypersensitivity reactions.

Sulfonylureas are potentially teratogenic and cannot be used in pregnancy or in patients who intend to get pregnant. Impairment of liver or kidney function increase the risk of hypoglycemia, and are contraindications. As other anti-diabetic drugs cannot be used either under these circumstances, insulin therapy is the only option in pregnancy and hepatic and renal failure.

Second generation sulfonylureas have increased potency by weight, compared to first generation sulfonylureas. They have decreased side effects but an increased cost.

Some rare cases of Type 1 diabetes have been found to react to this drug in a positive way

History

Sulfonylureas were discovered by the chemist Marcel Janbon and co-workers, who were studying sulfonamide antibiotics and discovered that the compound sulfonylurea induced hypoglycemia in animals (see also Patlak 2002). It was reported in: Janbon M, Chaptal J, Vedel A, Schaap J. Accidents hypoglycémiques graves par un sulfamidothiodiazol (le VK 57 ou 2254 RP). Montpellier Med. 1942;441:21-22.

Thiazolidinediones

The medication class of *thiazolidinedione* was introduced in the late 1990s as an adjunctive therapy for diabetes mellitus (type 2) and related diseases.

Mode of action

Thiazolidinediones or TZDs act by binding to PPARs (peroxisome proliferator-activated receptors), a group of receptor molecules inside the cell nucleus, specifically PPAR[3] (gamma). The normal ligands for these receptors are free fatty acids (FFAs) and eicosanoids.

When activated, the receptor migrates to the DNA, activating transcription of a number of specific genes.

Genes upregulated by PPAR^3 can be found in the main article on peroxisome proliferator-activated receptors.

By activating PPAR^3:

- insulin resistance is decreased

adipocyte differentiation is modified
VEGF-induced angiogenesis is inhibited (abstract).
Leptin levels decrease (leading to an increased appetite)
Levels of certain interleukins (e.g. IL-6) fall
Adiponectin levels rise

Members of the class

These include:

- rosiglitazone (Avandia)

pioglitazone (Actos)

Troglitazone was withdrawn from the market due to an increased incidence of drug-induced hepatitis in patients who were using the drug. It is now common practice that liver enzymes are monitored during the first year of treatment with the "newer" thiazolidinediones.

Experimental agents include MCC-555, a powerful antidiabetic agent and the early non-marketed thiazolidinedione ciglitazone.

Uses

The only registered use of the thiazolidinediones is in diabetes mellitus type 2.

It is being investigated experimentally in polycystic ovary syndrome (PCOS) and non-alcoholic steatohepatitis (NASH).

Several forms of lipodystrophy cause insulin resistance, which has responded favorably to thiazolidinediones.

Side effects and contraindications

The withdrawal of troglitazone has led to concerns of other thiazolidinediones increasing the risk of hepatitis. Guidelines now mention that for the first year of thiazolidinedione therapy, a two- or three-monthly check of liver enzymes is conducted to ascertain that no liver damage is occurring.

The main side effect of all thiazolidinediones is fluid retention, leading to edema, weight gain, and potentially aggravating heart failure. Therefore, thiazolidinediones cannot be prescribed in patients with decreased ventricular function (NYHA grade III and IV heart failure).

Anti-inflammatory agents

Anti-inflammatory refers to the property of a substance or treatment that reduces inflammation. Anti-inflammatory drugs make up one half of analgesics, remedying pain by reducing inflammation as opposed to opioids which affect the brain.

Steroidal anti-inflammatory drugs

Many steroids, specifically glucocorticoids, reduce inflammation by binding to cortisol receptors. These drugs are often referred to as corticosteroids, though that is a larger category.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs), alleviate pain by counteracting the cyclooxygenase (COX) enzyme. On its own COX enzyme synthesizes prostaglandins, creating inflammation. In whole the NSAIDs prevent the prostaglandins from ever being synthesized, reducing or eliminating the pain.

In addition to medical drugs, many herbs have anti-inflammatory qualities, including hyssop, Arnica montana which contains helenalin, a sesquiterpene lactone, and willow bark, which contains salicylic acid, a substance related to the active ingredient in aspirin.

On the other hand, there are analgesics like paracetamol, called acetaminophen in the U.S. and sold under the brand name of Tylenol, which are commonly associated with anti-inflammatory drugs but which have no anti-inflammatory effects.

Some are concerned about the long term usage of NSAIDs as they cause gastric erosions which can become stomach ulcers and in extreme cases result in death. The risk of death as a result of use of NSAIDs is 1 in 10,000 for young adults aged 16-45. The risk increases ten fold for those over 75.

Ice treatment

Applying ice to a tissue injury has an anti-inflammatory effect and is often suggested as an injury treatment and pain management technique for athletes.

Anti-inflammatory Foods

Due to concerns over the gastric problems caused by NSAIDs researchers are turning to more natural solutions to dealing with the problem of inflammation. One ingredient with a great future potential is capsaicin, a naturally occurring ingredient in chili peppers. Studies have shown some success in the control of pain and inflammation when capsaicin is applied topically.

Others advocate the consumption of anti-inflammatory foods as a means of controlling inflammation. Anti-inflammatory foods include most colorful fruits and vegetables, oily fish and certain nuts, seeds, herbs and spices. Those following an anti-inflammatory diet will

avoid refined oils and sugars, and show a preference for anti-inflammatory foods in their meal choices. Several types of "Smoker's Paradoxes" [29], i.e. cases where smoking appears to have specific beneficial effects, have been observed; often the actual mechanism remains undetermined. For instance, recent studies suggest that smokers require less frequent repeated revascularization after percutaneous coronary intervention (PCI) [29], [30]. Smoking appears to interfere with development of Kaposi's sarcoma [31], breast cancer among women carrying the very high risk BRCA gene [32], preeclampsia [33], and atopic disorders such as allergic asthma [34]. A plausible mechanism of action in these cases may be the nicotine in tobacco smoke acting as an anti-inflammatory agent [35] and interfering with the disease process.

Glucocorticoids

Glucocorticoids are a class of steroid hormones characterised by an ability to bind with the cortisol receptor and trigger similar effects. Glucocorticoids are distinguished from mineralocorticoids and sex steroids by the specific receptors, target cells, and effects. Technically, the term corticosteroid refers to both glucocorticoids and mineralocorticoids, but is often used as a synonym for glucocorticoid.

Cortisol (or hydrocortisone) is the most important human glucocorticoid. It is essential for life and regulates or supports a variety of important cardiovascular, metabolic, immunologic, and homeostatic functions. Glucocorticoid receptors are found in the cells of almost all vertebrate tissues.

Effects

The name *glucocorticoid* derives from early observations that these hormones were involved in glucose metabolism. In the fasted state, cortisol stimulates several processes that collectively serve to increase and maintain normal concentrations of glucose in blood. These effects include:

- Stimulation of gluconeogenesis, particularly in the liver: This pathway results in the synthesis of glucose from non-hexose substrates such as amino acids and lipids and is particularly important in carnivores and certain herbivores. Enhancing the expression of enzymes involved in gluconeogenesis is probably the best known metabolic function of glucocorticoids.
- Mobilization of amino acids from extrahepatic tissues: These serve as substrates for gluconeogenesis.
- Inhibition of glucose uptake in muscle and adipose tissue: A mechanism to conserve glucose.
- Stimulation of fat breakdown in adipose tissue: The fatty acids released by lipolysis are used for production of energy in tissues like muscle, and the released glycerol provide another substrate for gluconeogenesis.

Glucocorticoids have potent anti-inflammatory and immunosuppressive properties. This is particularly evident when they are administered at pharmacological doses, but also is important in normal immune responses. As a consequence, glucocorticoids are widely used as drugs to treat inflammatory conditions such as arthritis or dermatitis, and as adjunction therapy for conditions such as autoimmune diseases.

Glucocorticoids have multiple effects on fetal development. An important example is their role in promoting maturation of the lung and production of the surfactant necessary for extrauterine lung function. Mice with homozygous disruptions in the corticotropin-releasing hormone gene (see below) die at birth due to pulmonary immaturity.

Excessive glucocorticoid levels resulting from administration as a drug or hyperadrenocorticism have effects on many systems. Some examples include inhibition of bone formation, suppression of calcium absorption (both of which can lead to osteoporosis), delayed wound healing, muscle weakness and increased risk of infection. These observations suggest a multitude of less dramatic physiologic roles for glucocorticoids.

Mode of action

Glucocorticoids bind to the cytosolic glucocorticoid receptor. This type of receptor gets activated upon ligand binding. After a hormone binds to the corresponding receptor, the newly formed receptor-ligand complex translocates itself into the cell nucleus, where it binds to many glucocorticoid response elements (GRE) in the promoter region of the target genes. The opposite mechanism is called *transrepression*. The activated hormone receptor interacts with specific transcription factors and prevents the transcription of targeted genes. Glucocorticoids are able to prevent the transcription of any of immune genes, including the IL-2 gene.

The ordinary glucocorticoids do not distinguish among transactivation and transrepression and influence both the "wanted" immune and "unwanted" genes regulating the metabolic and cardiovascular functions. Currently, intensive research is aimed at discovering selectively acting glucocorticoids that will be able to repress only the immune system.

Pharmacologic properties

A variety of *synthetic glucocorticoids,* some far more potent than cortisol, have been created for therapeutic use. They differ in the pharmacokinetics (absorption factor, half-life, volume of distribution, clearance) and in pharmacodynamics (for example the capacity of mineralocorticoid activity: retention of sodium ($Na+$) and water; see also: renal physiology). Because they absorb well through the intestines, they are primarily administered per os (by mouth), but also by other ways like topically on skin. More than 90 per cent of them bind different plasma proteins, however with a different binding specificity. Endogenous glucocorticoids and some synthetic corticoids have high affinity to the protein transcortin (also called CBG, corticosteroid binding protein), while all of them bind albumin. In the liver, they quickly metabolise by conjugation with a sulfate or glucuronic acid and are secreted in the urine.

Glucocorticoid potency, duration of effect, and overlapping mineralocorticoid potency varies (Table).

Comparative steroid potencies

Name	Glucocorticoid potency	Mineralocorticoid potency	Duration of action ($t_{1/2}$ in hours)
Hydrocortisone	1	1	8
Cortisone acetate	0.8	0.8	oral 8, intramuscular 18+
Prednisone	3.5-5	0.8	16-36
Prednisolone	4	0.8	16-36
Methylprednisolone	5-7.5	0.5	18-40
Dexamethasone	25-80	0	36-54
Betamethasone	25-30	0	36-54
Triamcinolone	5	0	12-36
Beclometasone	8 puffs 4 times a day equals 14 mg oral prednisone once a day	-	-
Fludrocortisone acetate	15	200	-
Deoxycorticosterone acetate (DOCA)	0	20	-
Aldosterone	0.3	200-1000	-

Cortisol (hydrocortisone) is the standard of comparison for glucocorticoid potency. Hydrocortisone is the name used for pharmaceutical preparations of cortisol. Data refer to oral dosing, except when mentioned. Note that oral potency may be less than parenteral potency because significant amounts (up to 50% in some cases) may not be absorbed from the intestine. Note that fludrocortisone, DOCA, and aldosterone are not considered glucocorticoids and are included in this table to provide perspective on mineralocorticoid potency.

Physiologic replacement of glucocorticoid

Any glucocorticoid can be given in a dose that provides approximately the same glucocorticoid effects as normal cortisol production; this is referred to as physiologic, replacement, or maintenance dosing. This is approximately 6-12 mg/m**2**/day (m**2** refers to body surface area (BSA) and is a measure of body size; an average man is 1.7 m**2**).

Medical uses and effects of high dose glucocorticoids

In much higher doses (termed pharmacologic doses), glucocorticoids are used to suppress various allergic, inflammatory, and autoimmune disorders. They are also administered as posttransplantory immunosuppressants to prevent the acute transplant rejection and the graft-versus-host disease. Nevertheless, they do not prevent an infection and also inhibit later reparative processes.

Some drugs used are cortisol (hydrocortisone), prednisone and dexamethasone.

Immunosuppressive mechanism

Glucocorticoids suppress the cell-mediated immunity. They act by inhibiting genes that code for the cytokines IL-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8 and TNF-[3], the most important of which is the IL-2. Smaller cytokine production reduces the T cell proliferation.

Glucocorticoids also suppress the humoral immunity, causing B cells to express smaller amounts of IL-2 and of IL-2 receptors. This diminishes both B cell clone expansion and antibody synthesis. The diminished amounts of IL-2 also causes less T lymphocyte cells to be activated.

Since glucocorticoid is a steroid, it regulates transcription factors; another factor it down regulates is the expression of Fc receptors on macrophages, so there is a decreased phagocytosis of opsonised cells.

Antiinflammatory effects

Glucocorticoids influence all types of inflammatory events, no matter what their cause. They induce the lipocortin-1 (annexin-1) synthesis, which then binds to cell membranes preventing the phospholipase A2 from coming into contact with its substrate arachidonic acid. This leads to diminished eicosanoid production. The cyclooxygenase (both COX-1 and COX-2) expression is also suppressed, potentiating the effect. In other words, the two main products in inflammation Prostaglandins and Leukotrienes are inhibited by the action of Glucocorticoids.

Glucocorticoids also stimulate the lipocortin-1 escaping to the extracellular space, where it binds to the leukocyte membrane receptors and inhibits various inflammatory events: epithelial adhesion, emigration, chemotaxis, phagocytosis, respiratory burst and the release of various inflammatory mediators (lysosomal enzymes, cytokines, tissue plasminogen activator, chemokines etc.) from neutrophils, macrophages and mastocytes.

Side effects

Glucocorticoid drugs currently being used act nonselectively, so in the long run they may impair many healthy anabolic processes. To prevent this, much research has been focused recently on the elaboration of selectively acting glucocorticoid drugs. These are the side effects that could be prevented:

- immunosuppression

hyperglycemia due to increased gluconeogenesis, insulin resistance and impaired glucose tolerance ("steroid diabetes"); caution in those with diabetes mellitus

increased skin fragility, easy bruising

reduced bone density (osteoporosis, higher fracture risk, slower fracture repair)

weight gain due to increased visceral and truncal fat deposition (central obesity) and appetite stimulation

adrenal insufficiency (if used for long time and stopped suddenly without a taper)

muscle breakdown (proteolysis), weakness; reduced muscle mass and repair
expansion of malar fat pads and dilation of small blood vessels in skin
anovulation, irregularity of menstrual periods
growth failure, pubertal delay
increased plasma amino acids, increased urea formation; negative nitrogen balance
excitatory effect on central nervous system

In high doses, hydrocortisone (cortisol) and those glucocorticoids with appreciable mineralocorticoid potency can exert a mineralocorticoid effect as well, although in physiologic doses this is prevented by rapid degradation of cortisol by 11^2-hydroxysteroid dehydrogenase isoenzyme 2 (11^2-HSD2) in mineralocorticoid target tissues. Mineralocorticoid effects can include salt and water retention, extracellular fluid volume expansion, hypertension, potassium depletion, and metabolic alkalosis.

The combination of clinical problems produced by prolonged, excess glucocorticoids, whether synthetic or endogenous, is termed Cushing's syndrome.

Adrenal suppression and withdrawal

In addition to the effects listed above, use of high dose steroids for more than a week begins to produce suppression of the patient's adrenal glands because the exogenous glucocorticoids suppress hypothalamic corticotropin releasing hormone (CRH) and pituitary adrenocorticotropic hormone (ACTH). With prolonged suppression the adrenal glands atrophy (physically shrink) and can take months to recover full function after discontinuation of the exogenous glucocorticoid.

During this recovery time, the patient is vulnerable to adrenal insufficiency during times of stress, such as illness. While there is wide individual variation in suppressive dose and time for adrenal recovery, clinical guidelines have been devised to estimate potential adrenal suppression and recovery, to reduce risk to the patient. The following is one example, but many variations exist or may be appropriate in individual circumstances.

- If a patient has been receiving daily high doses for 5 days or less, they can be abruptly stopped (or reduced to physiologic replacement if patient is adrenal deficient). Full adrenal recovery can be assumed to occur by a week afterward.
- If high doses were used for 6-10 days, reduce to replacement dose immediately and taper over 4 more days. Adrenal recovery can be assumed to occur within 2-4 weeks of completion of steroids.
- If high doses were used for 11-30 days, cut immediately to twice replacement, and then by 25% every 4 days. Stop entirely when dose is less than half of replacement. Full adrenal recovery should occur within 1-3 months of completion of withdrawal.
- If high doses were used more than 30 days, cut dose immediately to twice replacement, and reduce by 25% each week until replacement is reached.
- Then change to oral hydrocortisone or cortisone as a single morning dose, and gradually decrease by 2.5 mg each week. When a.m. dose is less than

replacement, the return of normal basal adrenal function may be documented by checking 0800 cortisol levels prior to the morning dose; stop drugs when 0800 cortisol is 10 ¼g/dl. It is difficult to predict the time to full adrenal recovery after prolonged suppressive exogenous steroids; some people may take nearly a year.

- Flare-up of the underlying condition for which steroids are given may require a more gradual taper than outlined above.

Identifiers

CAS number 50-23-7

ATC code H02AB09 (and others)

PubChem 5754

Chemical data

Mol. weight 362.465

Therapeutic considerations

Pregnancy cat. C

Routes Oral tablets, intravenously, topical

Cortisol is a corticosteroid hormone produced by the adrenal cortex that is involved in the response to stress; it increases blood pressure, blood sugar levels, may cause infertility in women, and suppresses the immune system. In pharmacology, cortisol is referred to as Hydrocortisone, and is used to treat allergies and inflammation.

Synthesis

Cortisol is synthesized from pregnenolone. The change involves hydroxylation of C-11, C-17, and C-21, the oxidation of C-3, and the isomerization of the C-5 double bond to C-4. The synthesis takes place in the zona fasciculata of the cortex of the adrenal glands. While the

adrenal cortex produces aldosterone (in the zona glomerulosa) and some sex hormones (in the zona reticulosa), cortisol is its main secretion. (The name cortisol comes from cortex.) The medulla of the adrenal gland lies under the cortex and mainly secretes epinephrine and norepinephrine under sympathetic stimulation.

The synthesis of cortisol in the adrenal gland is stimulated by the anterior lobe of the pituitary gland with adrenocorticotropic hormone (ACTH); production of ACTH is in turn stimulated by corticotropin-releasing hormone (CRH), released by the hypothalamus.

Physiology

The amount of cortisol present in the serum undergoes diurnal variation, with the highest levels present in the early morning, and lower levels in the evening, several hours after the onset of sleep. Information about the light/dark cycle is transmitted from the retina to the paired suprachiasmatic nuclei in the hypothalamus. Changed patterns of serum cortisol levels have been observed in connection with abnormal ACTH levels, clinical depression, psychological stress, and such physiological stressors as hypoglycemia, illness, fever, trauma, surgery, fear, pain, physical exertion or extremes of temperature. There is also significant individual variation, although a given person tends to have consistent rhythms.

Cortisol also inhibits the secretion of corticotropin releasing hormone (CRH), resulting in feedback inhibition of ACTH secretion. Some researchers believe that this normal feedback system may break down when animals are exposed to chronic stress.

In normal release, cortisol has widespread actions which help restore homeostasis after stress. It acts as a physiological antagonist to insulin by promoting gluconeogenesis, breakdown of lipids, and proteins, and mobilization of extrahepatic amino acids and ketone bodies. This leads to increased blood glucose concentrations, resulting in increased glycogen formation in the liver (Freeman, 2002). It also increases blood pressure. The hormone lowers the activity of the immune system in the blood. It reflects leukocyte redistribution to lymph nodes, bone marrow, and skin (Cohen, 1972; Cox & Ford, 1982; Dhabhar & McEwen, 1996; Dhabhar and Dhabhar; Fauci, 1975; Fauci & Dale, 1974; Fauci & Dale, 1975; Yu et al., 1974). Acute administration of corticosterone (the endogenous Type I and Type II receptor agonist), or RU28362 (a specific Type II receptor agonist), to adrenalectomized animals induced changes in leukocyte distribution. Bone formation is also lowered by cortisol.

These normal endogenous functions are the basis for the physiological consequences of chronic stress - prolonged cortisol secretion causes muscle wastage, hyperglycemia, and suppresses immune / inflammatory responses. The same consequences arise from long-term use of glucocorticoid drugs.

Also, long-term exposure to cortisol results in damage to cells in the hippocampus. This damage results in impaired learning. However, short-term exposure of cortisol helps to create memories; this is the proposed mechanism for storage of flash bulb memories.

Most serum cortisol, all but about 4%, is bound to proteins including corticosteroid binding globulin (*CBG*), and albumin. Only free cortisol is available to most receptors.

THE DISORDERS OF CORTISOL SECRETION

	Plasma Cortisol	Plasma ACTH
Primary Hypercortisolism	↑	↓
Secondary Hypercortisolism (pituitary, Cushing Disease)	↑	↑
Primary Hypocortisolism (Addison Disease)	↓	↑
Secondary Hypocortisolism (pituitary)	↓	↓

Pharmacology

As an oral or injectable drug, cortisol is also known as hydrocortisone. It is used as an immunosuppressive drug, given by injection in the treatment of severe allergic reactions such as anaphylaxis and angioedema, in place of prednisolone in patients who need steroid treatment but cannot take oral medication, and peri-operatively in patients on long-term steroid treatment to prevent an Addisonian crisis.

It is given by topical application for its anti-inflammatory effect in allergic rashes, eczema and certain other inflammatory conditions. Brand names include Emocort®, Epifoam®, Sigmacort®, Hyderm®, NovoHydrocort® Cortoderm®, Cortizone-10®, Cortaid®, and Lanacort®

It may also be injected into inflamed joints resulting from diseases such as gout.

Compared to prednisolone, hydrocortisone is about 1/4th the strength. Dexamethasone is about 40 times stronger than hydrocortisone. For side effects, see corticosteroid and prednisolone.

Diseases

- *Hypercortisolism*: Excessive levels of cortisol in the blood result in Cushing's syndrome.
- *Hypocortisolism, or adrenal insufficiency*: If on the other hand the adrenal glands do not produce sufficient amounts of cortisol, Addison's disease is the consequence.

Antianginals

An *antianginal* is any drug used in the treatment of angina pectoris, a symptom of ischaemic heart disease.

Drugs used are nitrates such as nitroglycerin (glyceryl trinitrate) or pentaerythritol tetranitrate; beta blockers, either cardioselectives such as acebutolol or metoprolol, or non-cardioselectives such as oxprenolol or sotalol; or calcium channel blockers, either Class I agents (e.g., verapamil), Class II agents (e.g., amlodipine, nifedipine), or the Class III agent diltiazem.

Nitrates cause vasodilation of the venous capacitance vessels by simulating the endothelium-derived relaxing factor (EDRF). Used to relieve both exertional and vasospastic angina by allowing venous pooling, reducing the pressure in the ventricles and so reducing wall tension and oxygen requirements in the heart. Short-acting nitrates are used to abort angina attacks that have occurred, while longer-acting nitrates are used in the prophylactic management of the condition.

Beta blockers are used in the prophylaxis of exertional angina by reducing the work the heart is allowed to perform below the level that would provoke an angina attack. They cannot be used in vasospastic angina and can precipitate heart failure.

Calcium ion (Ca**++**) antagonists (Calcium channel blockers) are used in the treatment of both exertional and vasospastic angina. In vitro, they dilate the coronary and peripheral arteries and have negative inotropic and chronotropic effects - decreasing afterload, improving myocardial efficiency, reducing heart rate and improving coronary blood flow. In vivo, the vasodilation and hypotension trigger the baroreceptor reflex. Therefore the net effect is the interplay of direct and reflex actions. Class I antiarrhythmic agents have the most potent negative inotropic effect and may cause heart failure; Class II agents do not depress conduction or contractility; the Class III agent has negligible inotropic effect and causes almost no reflex tachycardia.

Beta blockers

Beta blockers (sometimes written as ^{2}*-blockers*) are a class of drugs used for various indications, but particularly for the management of cardiac arrhythmias and cardioprotection after myocardial infarction. Whilst once first-line treatment for hypertension, their role was downgraded in June 2006 in the United Kingdom to fourth-line as they perform less well than other drugs, particularly in the elderly, and there is increasing evidence that the most frequently used beta-blockers at usual doses carry an unacceptable risk of provoking type 2 diabetes.[1]

Beta blockers may also be referred to as *beta-adrenergic blocking agents*, *beta-adrenergic antagonists*, or *beta antagonists*.

Pharmacology

Beta blockers block the action of endogenous catecholamines,

There are three known types of beta receptor, designated ^{2}***1***, ^{2}***2*** and ^{2}***3***. ^{2}***1***-Adrenergic receptors are located mainly in the heart, kidney, and adipose tissue. ^{2}***2***-Adrenergic receptors are located mainly in the heart, lung, GI tract, liver, pancreas, and skeletal muscle. The role and location of ^{2}***3***-receptors is less well-defined.

2-Receptor antagonism

Stimulation of ^{2}***1*** receptors by epinephrine induces a positive chronotropic and inotropic effect on the heart and increases cardiac conduction velocity and automaticity. Stimulation of ^{2}2 receptors induces smooth muscle relaxation (resulting in vasodilation and bronchodilation amongst other actions), induces tremor in skeletal muscle, increases glycogenolysis in the liver and skeletal muscle.

Beta blockers inhibit these normal epinephrine-mediated sympathetic actions, but have minimal effect on resting subjects. That is, they reduce the effect of excitement/physical exertion on heart rate and force of contraction, dilation of blood vessels, opening of bronchi, reduce tremor, and breakdown of glycogen.

It is therefore somewhat unexpected that non-selective beta blockers have an antihypertensive effect, since they appear to cause vasoconstriction. The antihypertensive mechanism appears to involve: reduction in cardiac output (due to negative chronotropic and inotropic effects), reduction in renin release from the kidneys, and a central nervous system effect to reduce sympathetic activity.

Antianginal effects result from negative chronotropic and inotropic effects, which decrease cardiac workload and oxygen demand.

The antiarrhythmic effects of beta blockers arise from sympathetic nervous system blockade – resulting in depression of sinus node function and atrioventricular node conduction, and prolonged atrial refractory periods. Sotalol, in particular, has additional antiarrhythmic properties and prolongs action potential duration through potassium channel blockade.

Intrinsic sympathomimetic activity

Some beta blockers (e.g. oxprenolol and pindolol) exhibit intrinsic sympathomimetic activity (ISA). These agents are capable of exerting low level agonist activity at the ^{2}-adrenergic receptor while simultaneously acting as a receptor site antagonist. These agents, therefore, may be useful in individuals exhibiting excessive bradycardia with sustained beta blocker therapy.

Agents with ISA are not used post-myocardial infarction as they have not been demonstrated to be beneficial. They may also be less effective than other beta blockers in the management of angina and tachyarrhythmia (Rossi, 2006).

+-1-Receptor antagonism

Some beta blockers (e.g. labetalol and carvedilol) exhibit mixed antagonism of both ²- and ±***1***-adrenergic receptors, which provides additional arteriolar vasodilating action.

Other effects

Beta blockers decrease nocturnal melatonin release, perhaps partly accounting for sleep disturbance caused by some agents (Stoschitzky et al., 1999).

Clinical use

Large differences exist in the pharmacology of agents within the class, thus not all beta blockers are used for all indications listed below.

Indications for beta blockers include:

- Hypertension
- Angina
- Cardiac arrhythmia
- Congestive heart failure
- Myocardial infarction
- Glaucoma
- Migraine prophylaxis
- Symptomatic control (tachycardia, tremor) in anxiety and hyperthyroidism
- Essential tremor
- Phaeochromocytoma, in conjunction with ±-blocker

Beta blockers have also been used in the following conditions:

- Hypertrophic obstructive cardiomyopathy
- Acute dissecting aortic aneurysm
- Marfan syndrome (chronic treatment with propranolol slows progression of aortic dilation and its complications)
- Prevention of variceal bleeding in portal hypertension
- Possible mitigation of hyperhidrosis

Congestive heart failure

Although beta blockers were once contraindicated in congestive heart failure, as they have the potential to worsen the condition, studies in the late 1990s showed their positive effects on morbidity and mortality in congestive heart failure (Hjalmarson, 2000; Leizorovicz, 2002; Packer, 2002). Bisoprolol, carvedilol and sustained-release metoprolol are specifically indicated as adjuncts to standard ACE inhibitor and diuretic therapy in congestive heart failure.

Anxiety and performance enhancement

Some people, particularly musicians, use beta blockers to avoid stage fright and tremor during public performance and auditions. The physiological symptoms of the fight/flight response associated with performance anxiety and panic (pounding heart, cold/clammy hands, increased respiration, sweating, etc.) are significantly reduced, thus enabling anxious individuals to concentrate on the task at hand.

Currently, no beta blocker is approved for anxiolytic use by the US FDA. Still, use of beta blockers to combat the physical symptoms of anxiety is not uncommon, particularly among performers, and there are studies which confirm their efficacy as an anxiolytics. (Schneier 2006)

Since they lower heart rate and reduce tremor, beta blockers have been used by some Olympic marksmen to enhance performance, though beta blockers are banned by the International Olympic Committee (IOC).

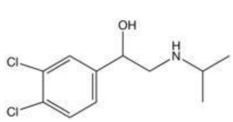
Adverse effects

Common adverse drug reactions (ADRs) associated with the use of beta blockers include: nausea, diarrhoea, bronchospasm, dyspnoea, cold extremities, exacerbation of Raynaud's syndrome, bradycardia, hypotension, heart failure, heart block, fatigue, dizziness, abnormal vision, decreased concentration, hallucinations, insomnia, nightmares, depression, sexual dysfunction, erectile dysfunction and/or alteration of glucose and lipid metabolism. Mixed ±1/^{2}-antagonist therapy is also commonly associated with orthostatic hypotension. Carvedilol therapy is commonly associated with oedema. (Rossi, 2006)

Central nervous system (CNS) adverse effects (hallucinations, insomnia, nightmares, depression) are more common in agents with greater lipid solubility, which are able to cross the blood-brain barrier into the CNS. Similarly, CNS adverse effects are less common in agents with greater aqueous solubility (listed below).

Adverse effects associated with ^{2}***2***-adrenergic receptor antagonist activity (bronchospasm, peripheral vasoconstriction, alteration of glucose and lipid metabolism) are less common with ^{2}***1***-selective (often termed "cardioselective") agents, however receptor selectivity diminishes at higher doses.

Examples of beta blockers



Dichloroisoprenaline, the first beta blocker.

Historical

- Dichloroisoprenaline

Practolol
Pronethaolol

Non-selective agents

- Alprenolol
Carteolol
Levobunolol
Mepindolol
Metipranolol
Nadolol
Oxprenolol
Penbutolol
Pindolol
Propranolol
Sotalol
Timolol

21-Selective agents

- Acebutolol
Atenolol
Betaxolol
Bisoprolol
Esmolol
Metoprolol
Nebivolol

Mixed +-1/2-adrenergic antagonists

- Carvedilol
Celiprolol
Labetalol

22-Selective agents

- Butoxamine (weak ±-adrenergic agonist activity)

Comparative information

Pharmacological differences

- Agents with intrinsic sympathomimetic action (ISA)
  - Acebutolol, carteolol, celiprolol, mepindolol, oxprenolol, pindolol
- Agents with greater aqueous solubility
  - Atenolol, celiprolol, nadolol, sotalol

- Agents with membrane stabilising activity
  - Acebutolol, betaxolol, pindolol, propranolol
- Agents with antioxidant effect
  - Carvedilol

Indication differences

- Agents specifically indicated for cardiac arrhythmia
  - Esmolol, sotalol
- Agents specifically indicated for congestive heart failure
  - Bisoprolol, carvedilol, sustained-release metoprolol
- Agents specifically indicated for glaucoma
  - Betaxolol, carteolol, levobunolol, metipranolol, timolol
- Agents specifically indicated for myocardial infarction
  - Atenolol, metoprolol, propranolol
- Agents specifically indicated for migraine prophylaxis
  - Timolol, propranolol

Propranolol is the only agent indicated for control of tremor, portal hypertension and oesophageal variceal bleeding, and used in conjunction with ±-blocker therapy in phaeochromocytoma (Rossi, 2006).

Calcium channel blockers

Calcium channel blockers are a class of drugs with effects on many excitable cells of the body, like the muscle of the heart, smooth muscles of the vessels or neuron cells. The latter are used as antiepileptics and are not covered in this article.

The main action of calcium channel blockers is to lower the blood pressure. It is for this action that it is used in individuals with hypertension.

Most calcium channel blockers decrease the force of contraction of the myocardium (muscle of the heart). This is known as the negative inotropic effect of calcium channel blockers. It is because of the negative inotropic effects of most calcium channel blockers that they are avoided (or used with caution) in individuals with cardiomyopathy

Many calcium channel blockers also slow down the conduction of electrical activity within the heart, by blocking the calcium channel during the plateau phase of the action potential of the heart (see: cardiac action potential). This causes a lowering of the heart rate and may cause heart blocks. This is known as the negative chronotropic effect of calcium channel blockers. The negative chronotropic effects of calcium channel blockers make them a commonly used class of agents in individuals with atrial fibrillation or flutter in whom control of the heart rate is an issue.

Mechanism of action

Calcium channel blockers work by blocking voltage-sensitive calcium channels in the heart and in the blood vessels. This prevents calcium levels from increasing as much in the cells when stimulated, leading to less contraction.

This decreases total peripheral resistance by dilating the blood vessels, and decreases cardiac output by lowering the force of contraction. Because resistance and output drop, so does blood pressure.

With low blood pressure, the heart does not have to work as hard; this can ease problems with cardiomyopathy and coronary disease.

Unlike with beta-blockers, the heart is still responsive to sympathetic nervous system stimulation, so blood pressure can be maintained more effectively.

List of calcium channel blockers

Dihydropyridine calcium channel blockers

- Amlodipine **(Norvasc)**
- Felodipine (Plendil)
Nicardipine (Cardene, Carden SR)
Nifedipine (Procardia, Adalat)
Nimodipine (Nimotop)
Nisoldipine (Sular)
Nitrendipine (Cardif, Nitrepin)
Lacidipine (Motens)
Lercanidipine (Zanidip)

Phenylalkylamine calcium channel blockers

- Verapamil (Calan, Isoptin)
Gallopamil (D600)

Benzothiazepine calcium channel blockers

- Diltiazem (Cardizem)

Other

- Menthol (mint oil)

Other drugs with similar uses

Other classes of pharmaceutical agents that have overlapping effects as calcium channel blockers include ACE inhibitors, beta-blockers, and nitrates.

Amlodipine (Norvasc)

***Amlodipine* Systematic (IUPAC) name**

3-ethyl-5-methyl-2-(2-aminoethoxymethyl)-4-(2- chlorophenyl)-1,4-dihydro-6-methyl-3,5-pyridinedicarboxylate benzenesulfonate

Identifiers

CAS number 88150-42-9

ATC code **C08**CA01

PubChem 2162

DrugBank APRD00520

Chemical data

Formula $C_{20}H_{25}ClN_2O_5.C_6H_6O_3S$

Mol. weight 408.879 g/mol

Pharmacokinetic data

Bioavailability 64 to 90%

Metabolism Hepatic

Half life 30 to 50 hours

Excretion Renal

Therapeutic considerations

Pregnancy cat. $C_{(AU)}$ $C_{(US)}$

Legal status $POM_{(UK)}$ $_{-only(US)}$

Routes Oral (tablets)

Amlodipine (as besylate, mesylate or maleate) is a long-acting calcium channel blocker used as an anti-hypertensive and in the treatment of angina. Amlodipine is marketed as *Norvasc*® in North America and as *Istin*® in the United Kingdom as well as under various other names. As other calcium channel blockers, amlodipine acts by relaxing the smooth muscle in the arterial wall, decreasing peripheral resistance and hence improving blood pressure; in angina it improves blood flow to the myocardium. It was developed under the direction of Dr. Simon Campbell.

Indications

- hypertension
prophylaxis of angina

Cautions

- hepatic impairment
pregnancy

Contra-indications

- cardiogenic shock
unstable angina
significant aortic stenosis
breast feeding

Side effects

Some side effects of the use of amlodipine may be:

- Very often: peripheral edema (feet and ankles) - in 1 of 10 users
Often: dizziness, palpitations, muscle, stomach or headache, dyspepsia, nausea - in 1 in 100 users
Sometimes: blood disorders, development of breasts in men (gynecomastia), impotence, depression, insomnia, tachycardia - in 1 in 1,000 users
Rarely: erratic behavior, hepatitis, jaundice - in 1 in 10,000 users
Very rarely: hyperglycemia, tremor, Stevens-Johnson syndrome - in 1 in 100,000 users

Source: Sandoz product information sheet

Dose

- Hypertension or angina: 5 or 10 mg once daily.

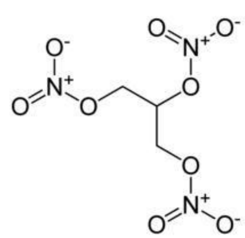
Salts

In the United Kingdom tablets of amlodipine from different suppliers may contain different salts. The strength of the tablets is expressed in terms of amlodipine base. i.e. without the salt. Tablets containing different salts are therefore considered interchangeable.

Patent Loss

Pfizer patent protection on Norvasc until 2007.

Nitroglycerin



Propane-1,2,3-triyl trinitrate
IUPAC name

Chemical formula $C_3H_5N_3O_9$

Molecular mass 227.0872 g/mol

Shock sensitivity Very high

Friction sensitivity Very high

Density 1.13 kg/dm^3 at 15 °C

Explosive velocity 7700 m/s

RE factor 1.50

Melting point 13.2 °C (55.76 °F)

Autoignition temperature Decomposes at 50 to 60 °C (122 to 140 °F)

Appearance Clear yellow/colorless oily liquid

CAS number 55-63-0

PubChem 4510

SMILES
C(C(CO[N+](=O)[O-])O
[N+](=O)[O-])O[N+](=O)[O-]

Nitroglycerin, also known as *nitroglycerine*, *trinitroglycerin*, and *glyceryl trinitrate*, is a chemical compound. It is a heavy, colorless, addictive, oily, explosive liquid obtained by nitrating glycerol. It is used in the manufacture of explosives, specifically dynamite, and as such is employed in the construction and demolition industries. It is also used medically as a vasodilator to treat heart conditions.

History

Nitroglycerin was discovered by chemist Ascanio Sobrero in 1847, working under TJ Pelouze at the University of Torino. The best manufacturing process was developed by Alfred Nobel in the 1860s. His company exported a liquid combination of nitroglycerin and gunpowder as 'Swedish Blasting Oil', but the extreme danger as a result of its extreme

instability, as shown in a number of "appalling catastrophes," led to the liquid being widely banned and to the development of dynamite (and similar mixtures such as dualine and lithofracteur), mixing the nitroglycerine with inert (Nobel used kieselguhr) or combustible absorbents (e.g., nitrocellulose to produce the yellow gel, blasting gelatine).

Instability and desensitization

In its pure form, it is a contact explosive (i.e., physical shock can cause it to explode) and degrades over time to even more unstable forms. This makes it highly dangerous to transport or use. In this undiluted form it is one of the most powerful high explosives, comparable to the military explosives RDX and PETN (which are not used in munitions at full concentration because of their sensitivity) as well as the plastic explosive C-4.

Early in the history of this explosive it was discovered that liquid nitroglycerin can be "desensitized" by cooling to 5 to 10 °C (40 to 50 °F), at which temperature it freezes, contracting upon solidification. However, later thawing can be extremely sensitizing, especially if impurities are present or if warming is too rapid. It is possible to chemically "desensitize" nitroglycerin to a point where it can be considered approximately as "safe" as modern High Explosive formulations, by the addition of approximately 10 to 30% ethanol, acetone, or dinitrotoluene (percentage varies with the desensitizing agent used). Desensitization requires extra effort to reconstitute the "pure" product. Failing this, it must be assumed that desensitized nitroglycerin is substantially more difficult to detonate, possibly rendering it useless as an explosive for practical application.

A serious problem in the use of nitroglycerin results from its high freezing point (13 °C [55 °F]). Solid nitroglycerin is much less sensitive to shock than the liquid, a feature common in explosives and in the past it has often been shipped in the frozen state, but this has resulted in a high number of accidents during the thawing process by the end user just prior to use. This disadvantage is overcome by using mixtures of nitroglycerin with other polynitrates; for example, a mixture of nitroglycerin and ethylene glycol dinitrate freezes at -29 °C (-20 °F).[1]

Detonation

Nitroglycerin and any or all of the diluents mentioned above can certainly deflagrate or burn. However, the explosive power of nitroglycerin is derived from detonation: energy from the initial decomposition causes a pressure gradient which detonates the surrounding fuel. This can generate a self-sustained shock-wave that propagates through the fuel-rich medium at or above the speed of sound as a cascade of near-instantaneous pressure-induced decomposition of the fuel into gas. This is quite unlike deflagration, which depends solely upon available fuel, regardless of pressure or shock.

Preparation

Nitroglycerin is prepared by nitration of glycerol (also known as glycerin). In the process, glycerin is slowly tipped into a mix of full concentration nitric and sulfuric acids (about 50% sulfuric acid, 40% nitric acid, and 5-10% glycerin). The mixed acid must be cooled to

approximately room temperature before the glycerin is added because they exotherm (heat up) greatly when combined. The solution is slowly stirred. A few seconds after mixing, the vessel must be immersed in a jacket of ice water to prevent the exothermic reaction from overheating it, causing nitric acid decomposition or even explosion. The temperature should never exceed 30 °C (86 °F), but the chemicals must not be cooled by the ice water before mixing, or the nitrating reaction will not take place.

If the reaction is successful, the nitroglycerin will form a slightly yellow or straw colored liquid which will float to the top of the acid mix. The mix is then carefully poured into a large container of water. The nitroglycerin will settle to the bottom (it is water insoluble) and should be neutralized with sodium carbonate and water mix until its pH becomes neutral.

Manufacturing

The industrial manufacturing process often uses a nearly 50:50 mixture of sulfuric acid and nitric acid. This can be produced by mixing white fuming nitric acid (quite costly pure nitric acid in which oxides of nitrogen have been removed, as apart from red fuming nitric acid) and concentrated sulfuric acid. More often, this mixture is attained by the cheaper method of mixing fuming sulfuric acid (sulfuric acid containing excess sulfur trioxide) and azeotropic nitric acid (consisting of around 70% nitric acid, the rest being water).

The sulfuric acid produces protonated nitric acid species, which are attacked by glycerin's nucleophilic oxygen atoms. The nitro group is thus added as an ester C-O-NO2 and water is produced. This is apart from an aromatic nitration reaction in which nitronium ions are the active species in an electrophilic attack of the molecules ring system.

The addition of glycerin results in an exothermic reaction (i.e., heat is produced), as usual for mixed acid nitrations. However, if the mixture becomes too hot, it results in runaway, a state of accelerated nitration accompanied by the destructive oxidizing of organic materials of nitric acid and the release of very poisonous brown nitrogen dioxide gas at high risk of an explosion. Thus, the glycerin mixture is added slowly to the reaction vessel containing the mixed acid (not acid to glycerin as one might expect). The nitrator is cooled with cold water or some other coolant mixture and maintained throughout the glycerin addition at about 22 °C, much below which the esterification occurs too slowly to be useful. The nitrator vessel, often constructed of iron or lead and generally stirred with compressed air, has an emergency trap door at its base, which hangs over a large pool of very cold water and into which the whole reaction mixture (called the charge) can be dumped to prevent an explosion, a process referred to as drowning. If the temperature of the charge exceeds about 30 °C (actual value varying by country) or brown fumes are seen in the nitrators vent, then it is immediately drowned.

Due to the great dangers associated with its production, most nitroglycerin production facilities are in offshore rigs or very remote locations.

Medical use

In medicine, nitroglycerin (sometimes called Glyceryl trinitrate, presumably to avoid alarming people) is used as a heart medication (under the trade names *Nitrospan®* and

Nitrostat®). It is used as a medicine for angina pectoris (ischaemic heart disease) in tablets, ointment, solution for intravenous use, transdermal patches (*Transderm Nitro*®, *Nitro-Dur*®), or sprays administered under the tongue (*Nitrolingual Pump Spray*®, *Natispray*®). A recent medical development will include a small amount of nitroglycerin in the tip of a new Durex condom to stimulate erection during intercourse. "The CSD500 condom contains a chemical in its teat, called glyceryl trinitrate (GTN), which is absorbed by the skin and causes blood vessels to dilate." According to anecdotal evidence, Nitroglycerin patches have also found use as treatment for the bite of the Brown recluse spider, which has a vasoconstricting venom. However, research has suggested that Nitroglycerin has negligible benefits and might even increased inflammation of the bite wound.

The principal action of nitroglycerin is vasodilation -- that is, widening of the blood vessels. The main effects of nitroglycerin in episodes of angina pectoris are

- subsiding of chest pain
- decrease of blood pressure
- increase of heart rate.

These effects arise because nitroglycerin is converted to nitric oxide in the body (by a mechanism that is not completely understood), and nitric oxide is a natural vasodilator. Recently, it has also become popular in an off-label use at reduced (0.2%) concentration in ointment form as an effective treatment for anal fissure.

Humans develop a tolerance and addiction to nitroglycerin after long-term exposure. Withdrawal symptoms include headaches, heart problems, and even death; with re-exposure to nitroglycerin these symptoms may disappear. For workers in nitroglycerin manufacturing facilities, this can result in a "Monday Morning Headache" phenomena for those who experience regular nitroglycerin exposure in the workplace; over the weekend they develop symptoms of withdrawal, which are then countered by reexposure on the next work day.

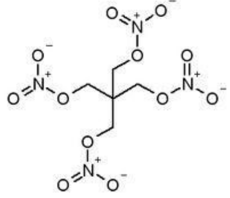
PETN



PETN

1,3-Dinitrato-2,2-bis (nitratomethyl)propane
IUPAC name

Chemical formula C5H8N4O12

Molecular mass 316.14 g/mol

Shock sensitivity Medium

Friction sensitivity Medium

Density 1.773 kg/m^3 at 20 °C

Explosive velocity 8,400 m/s

RE factor 1.66

Melting point 141.3 °C

Autoignition temperature Decomposes at 190 °C

Appearance Odourless white, crystalline solid.

CAS number 78-11-5

PETN (Pentaerythritol Tetranitrate, also known as Penthrite) is one of the strongest known high explosives, with a relative effectiveness factor (R.E. factor) of 1.66. It is more sensitive to shock or friction than TNT or tetryl, and it is never used alone as a booster. It is primarily used in booster and bursting charges of small caliber ammunition, in upper charges of detonators in some land mines and shells, and as the explosive core of detonation cord.

PETN is one of the explosive ingredients used in Semtex plastic explosive. During World War II the M9A1 2.36" Rocket Launcher (Bazooka) shaped charge, with 8 oz of pentolite (a mixture of PETN and TNT), could penetrate up to 5 inches of armor.

Demolition charge, M118, commonly called Flex-X or sheet explosive, consists of 4 half-pound sheets of flexible explosive packed in a plastic envelope. Each sheet is approximately 3 inches wide, 12 inches long, and ¼ inch thick. Note: The exact explosive contained in an M118 charge varies with the manufacturer. At present, some manufacturers use PETN as the basic explosive. Others use RDX. Charges manufactured in the future may include other explosives.

PETN is also used as a vasodilator. The medicine for heart diseases, "Lentonitrat", is pure PETN.

PETN was also used by Richard Reid for the plot to destroy American Airlines Flight 63 by trying to ignite explosives hidden in his shoes.

Properties

The velocity of detonation of PETN at a density of 1.7 is 8,400 meters per second.

PETN's formula is $C(CH_2ONO_2)_4$. Its theoretical maximum crystal density is 1.773 g/cm^3. It melts toward 141 °C.

As a pollutant in the environment

PETN does not occur naturally, so the production and use of this kind of compound can lead to contamination of the environment. PETN is subject to biodegradation in untreated or unpreserved urine and feces. There also have been some reports of its degradation by bacteria, whose PETN reductase denitrates PETN into trinitrates and then dinitrates (French et al., 1996). The last compound shown in the pathway, pentaerythritol dinitrate, is degraded further to unknown products.

Production

PETNs' preparation involves the nitration of pentaerythritol with a mixture of concentrated nitric and sulfuric acid. The preferred method of nitration is the ICI method, which utilizes concentrated nitric acid (98%+) alone, as mixed acid can create unstable sulfonated by-products.

$C(CH_2OH)_4 + 4HNO_3$ ’ $C(CH_2ONO_2)_4 + 4H_2O$

Antiarrhythmic agents

Antiarrhythmic agents are a group of pharmaceuticals that are used to suppress fast rhythms of the heart (cardiac arrhythmias), such as atrial fibrillation, atrial flutter, ventricular tachycardia, and ventricular fibrillation.

While the use of antiarrhythmic agents to suppress atrial arrhythmias (atrial fibrillation and atrial flutter) is still in practice, it is unclear whether suppression of atrial arrhythmias will prolong life [1][2].

In the past, it was believed that suppression of the potentially dangerous ventricular arrhythmias, ventricular tachycardia and ventricular fibrillation would prolong life, but it was found in large clinical trials that suppression of these arrhythmias would paradoxically increase mortality[3][4], which may happen due to the increased workload these drugs place on the heart.

In individuals with atrial fibrillation, antiarrhythmics are still used to suppress arrhythmias. This is often done to relieve the symptoms that may be associated with the loss of the atrial component to ventricular filling (atrial kick) that is due to atrial fibrillation or flutter.

In individuals with ventricular arrhythmias, antiarrhythmic agents are often still in use to suppress arrhythmias. In this case, the patient may have frequent arrhythmic events or be at high risk for ventricular arrhythmias. Antiarrhythmic agents may be considered the first-line therapy in the prevention of sudden death in certain forms of structural heart disease, and failure of these agents to suppress arrhythmias may lead to implantation of an implantable cardioverter-defibrillator (ICD).

The use of antiarrhythmic agents in this population may be in conjunction with an ICD. In this case, the ICD is used to prevent sudden death due to ventricular fibrillation, while the antiarrhythmic agent(s) are used to suppress ventricular tachyarrhythmias so that the ICD doesn't shock the patient frequently.

Many attempts have been made to classify antiarrhythmic agents. The problem arises from the fact that many of the antiarrhythmic agents have multiple modes of action, making any classification imprecise.

Vaughan Williams antiarrhythmic classification

The Vaughan Williams classification is one of the most widely used classification schemes for antiarrhythmic agents. This scheme classifies a drug based on the primary mechanism of its antiarrhythmic effect. However, its dependence on primary mechanism is one of the limitations of the VW classification, since many antiarrhythmic agents have multiple action mechanisms. Amiodarone, for example, has effects consistent with all of the first four classes. Another limitation is the lack of consideration within the VW classification system for the effects of drug metabolites. Procainamide—a class Ia agent whose metabolite N-acetyl procainamide (NAPA) has a class III action—is one such example. A historical limitation was that drugs such as digoxin and adenosine – important antiarrhythmic agents – had no place at all in the VW classification system. This has since been rectified by the inclusion of class V.

There are five main classes in the Vaughan Williams classification of antiarrhythmic agents:

- Class I agents interfere with the sodium (Na+) channel.
- Class II agents are anti-sympathetic nervous system agents. All agents in this class are beta blockers.
- Class III agents affect potassium (K+) efflux.
- Class IV agents affect the AV node.
- Class V agents work by other or unknown mechanisms.

Class I agents

The class I antiarrhythmic agents interfere with the sodium (Na+) channel. Class I agents are grouped by what effect they have on the Na+ channel, and what effect they have on cardiac action potentials.

Class Ia agents

Class Ia agents block the fast sodium channel. Blocking this channel depresses the phase 0 depolarization (reduces V***max***), which prolongs the action potential duration by slowing conduction. Agents in this class also cause decreased conductivity and increased refractoriness.

Indications for Class Ia agents are supraventricular tachycardia, ventricular tachycardia, symptomatic ventricular premature beats, and prevention of ventricular fibrillation.

Procainamide can be used in the treatment of atrial fibrillation in the setting of Wolff-Parkinson-White syndrome, and in the treatment of wide complex hemodynamically stable tachycardias.

While procainamide and quinidine may be used in the conversion of atrial fibrillation to normal sinus rhythm, they should only be used in conjunction with an AV node blocking agent (ie: digoxin, verapamil, or a beta blocker), because procainamide and quinidine can increase the conduction through the AV node and may cause 1:1 conduction of atrial fibrillation, causing an increase in the ventricular rate.

Class Ia agents include quinidine, procainamide and disopyramide.

Class Ib agents

Class Ib antiarrhythmic agents are sodium channel blockers. Class Ib agents have fast onset and offset kinetics, meaning that they have little or no effect at slower heart rates, and more effects at faster heart rates. Class Ib agents shorten the action potential duration and reduce refractoriness. These agents will decrease V***max*** in partially depolarized cells with fast response action potentials. They either do not change the action potential duration, or they may decrease the action potential duration.

Class Ib agents are indicated for the treatment of ventricular tachycardia and symptomatic premature ventricular beats, and prevention of ventricular fibrillation.

Class Ib agents include lidocaine, mexiletine, tocainide, and phenytoin.

Class Ic agents

Class Ic antiarrhythmic agents markedly depress the phase 0 depolarization (decreasing V***max***). They decrease conductivity, but have a minimal effect on the action potential duration. Of the sodium channel blocking antiarrhythmic agents (the class I antiarrhythmic agents), the class Ic agents have the most potent sodium channel blocking effects.

Class Ic agents are indicated for life-threatening ventricular tachycardia or ventricular fibrillation, and for the treatment of refractory supraventricular tachycardia (ie: atrial fibrillation).It can be toxic and can affect the reproductive system.

Class Ic agents include encainide, flecainide, moricizine, and propafenone.

Class II agents

Class II agents are conventional beta blockers. They act by selectively blocking the effects of catecholamines at the ^{2}1-adrenergic receptors, thereby decreasing sympathetic activity on the heart. These agents are particularly useful in the treatment of supraventricular tachycardias. They decrease conduction through the AV node.

Class II agents include esmolol, propranolol, and metoprolol.

Class III agents

Class III agents predominantly block the potassium channels, thereby prolonging repolarization[5]. Since these agents do not affect the sodium channel, conduction velocity is not decreased. The prolongation of the action potential duration and refractory period, combined with the maintenance of normal conduction velocity, prevent re-entrant arrhythmias. (The re-entrant rhythm is more like to interact with tissue that has become refractory).

Class III antiarrhythmic agents exhibit reverse use dependent prolongation of the action potential duration (*Reverse use-dependence*). This means that the refractoriness of the ventricular myocyte increases at lower heart rates. This increases the susceptibility of the myocardium to early after-depolarizations (EADs) at low heart rates. Antiarrhythmic agents that exhibit reverse use-dependence are more efficacious at preventing a tachyarrhythmia than converting someone into normal sinus rhythm. Because of the reverse use-dependence of class III agents, at low heart rates class III antiarrhythmic agents may paradoxically be more arrhythmogenic.

Amiodarone is indicated for the treatment of refractory VT or VF, particularly in the setting of acute ischemia. Amiodarone is also safe to use in individuals with cardiomyopathy and atrial fibrillation, to maintain normal sinus rhythm.

Sotalol is indicated for the treatment of atrial or ventricular tachyarrhythmias, and AV re-entrant arrhythmias. Ibutilide is the only antiarrhythmic agent currently approved by the Food and Drug Administration for acute conversion of atrial fibrillation to sinus rhythm.

Class III agents include amiodarone, azimilide, bretylium, clofilium, dofetilide, tedisamil, ibutilide, sematilide, and sotalol.

Class IV agents

Class IV agents are slow calcium channel blockers. They decrease conduction through the AV node.

Class IV agents include verapamil and diltiazem.

Class V agents

Class V agents include adenosine and digoxin. Digoxin increases vagal activity via its central action on the central nervous system, thus decreasing the conduction of electrical impulses through the AV node

Cardiac glycosides

Cardiac glycosides are drugs used in the treatment of congestive heart failure and cardiac arrhythmia. These glycosides are found as secondary metabolites in several plants, but also in some animals. Some of these compounds (ouabain and some frog poisons) are used in Africa as arrow-poisons for hunting.

Cardiac glycosides work by inhibiting the Na^{+}/K^{+} pump. They do this by stabilizing the E2-P transition state of the Na^{+}/K^{+} pump. This inhibition increases the amount of Ca^{++} ions available for contraction of the heart muscle, improves cardiac output and reduces distention of the heart.

They have an antiarrhythmic effect by prolonging the refractory period of the AV node (Atrioventricular node), reducing the number of impulses reaching the ventricles. Cardiac output is restored but atrial fibrillation or atrial flutter are not abolished.

Examples of plants producing cardiac glycosides:

- Strophanthus - ouabain g/k/e-strophanthin
- Digitalis lanata and Digitalis purpurea - digoxin, digitoxin
- Scilla maritima - proscillaridine A
- Adonis vernalis, Adonis aestivalis
- Acokanthera oblongifolia
- Convallaria

Some frog-poison contain bufalin, marinobufagenin and bufadienolides, cardiac glycosides.

Digoxin (INN) (IPA: [djÈd'Rksjn]) is a cardiac glycoside extracted from the foxglove plant, digitalis. Its corresponding aglycone is digoxigenin. Digoxin is widely used in the treatment of various heart conditions, namely atrial fibrillation, atrial flutter and congestive heart failure that cannot be controlled by other medication. Digoxin preparations are commonly marketed under the trade name *Lanoxin*.

Actions

The main pharmacological effects of digoxin are on the heart. Extracardiac effects are responsible for many of the adverse effects (see below).

Its main cardiac effects are

- A decrease of conduction of electrical impulses through the AV node, making it a commonly used drug in controlling the heart rate during atrial fibrillation or atrial flutter.
- An increase of force of contraction via inhibition of the Na^{+}/K^{+} ATPase pump (see below).

Mechanism of action

Digoxin binds to a site on the extracellular aspect of the ±-subunit of the Na±/K± ATPase pump in the membranes of heart cells (myocytes). This causes an increase in the level of sodium ions in the myocytes, which then leads to a rise in the level of calcium ions. The proposed mechanism is the following: inhibition of the Na±/K± pump leads to increased Na± levels, which in turn slows down the extrusion of Ca2+ via the Na±/Ca2+ exchange pump. Increased amounts of Ca2+ are then stored in the sarcoplasmic reticulum and released by each action potential, which is unchanged by digoxin. This is a different mechanism from that of catecholamines.

Digoxin also increases vagal activity via its central action on the central nervous system, thus decreasing the conduction of electrical impulses through the AV node. This is important for its clinical use in different arrhythmias (see below).

Clinical use

Today, the most common indications for digoxin are probably atrial fibrillation and atrial flutter with rapid ventricular response. High ventricular rate leads to insufficient diastolic filling time. By slowing down the conduction in the AV node and increasing its refractory period, digoxin can reduce the ventricular rate. The arrhythmia itself is not affected, but the pumping function of the heart improves owing to improved filling.

The use of digoxin in congestive heart failure during sinus rhythm is controversial. In theory the increased force of contraction should lead to improved pumping function of the heart, but its effect on prognosis is disputable and digoxin is no longer the first choice for congestive heart failure. However, it can still be useful in patients who remain symptomatic despite proper diuretic and ACE inhibitor treatment.

Digoxin is usually given by mouth, but can also be given by IV injection in urgent situations (the IV injection should be slow, heart rhythm should be monitored). The half life is about 36 hours, digoxin is given once daily, usually in 125 ¼g or 250 ¼g dosing. In patients with decreased kidney function the half life is considerably longer, calling for a reduction in dosing or a switch to a different glycoside (such as digitoxin which although having a much longer elimination half-life of around 7 days, is mainly eliminated from the body via the liver, and thus not affected by changes in renal function).

Effective plasma levels are fairly well defined, 1-2.6 nmol/l. In suspected toxicity or ineffectiveness, digoxin levels should be monitored. Plasma potassium levels also need to be closely controlled (see side effects below).

Adverse effects

The occurrence of adverse drug reactions is common, owing to its narrow therapeutic index (the margin between effectiveness and toxicity). Adverse effects are concentration-dependent, and are rare when plasma digoxin concentration is <0.8 ¼g/L. [1] They are also more common in patients with low potassium levels (hypokalemia), since digoxin normally competes with K± ions for the same binding site on the Na±/K± ATPase pump.

Common adverse effects (e1% of patients) include: loss of appetite, nausea, vomiting, diarrhoea, blurred vision, visual disturbances (yellow-green halos), confusion, drowsiness, dizziness, nightmares, agitation, and/or depression. Less frequent adverse effects (0.1%–1%) include: acute psychosis, delirium, amnesia, shortened QRS complex, atrial or ventricular extrasystoles, paroxysmal atrial tachycardia with AV block, ventricular tachycardia or fibrillation, heart block [1] but when sytematically sought, the evidence for this is equivocal.[2]

The pharmacological actions of digoxin usually results in electrocardiogram (ECG) changes, including ST depression or T wave inversion, which do not indicate toxicity. PR interval prolongation, however, may be a sign of digoxin toxicity. Additionally, increased intracellular Ca2+ may cause a type of arrhythmia called bigeminy (coupled beats), eventually ventricular tachycardia or fibrillation. The combination of increased (atrial) arrhythmogenesis and inhibited atrio-ventricular conduction (for example paroxysmal atrial tachycardia with A-V block - so-called "PAT with block") is said to be pathognomonic (i.e. diagnostic) of digoxin toxicity.[3]

An often described but rarely seen adverse effect of digoxin is a disturbance of colour vision (mostly yellow and green colour) called xanthopsia.

Digoxin has an interaction with the antimalarial medication Hydroxychloroquine.

Other information

Digoxin has potentially dangerous interaction with verapamil, amiodarone and erythromycin.

In overdose, the usual supportive measures are needed. If arrhythmias prove troublesome, or malignant hyperkalaemia occurs (inexorably rising potassium level due to paralysis of the cell membrane bound ATPase-dependant Na/K pumps), the specific antidote is antidigoxin (antibody fragments against digoxin, trade name Digibind®). [4] Digoxin is not usefully removed by hemodialysis.

Some physical properties of digoxin are water solubility of 64.8 mg/L at 25 °C and melting point at 249.3 °C.

In the news

Charles Cullen admitted in 2003 to killing as many as 40 hospital patients with overdoses of heart medication - usually digoxin - at hospitals in New Jersey and Pennsylvania over his 16-year career as a nurse. On March 10, 2006 he was sentenced to 18 consecutive life sentences and is not eligible for parole for 397 years. [3]

Adenosine

Adenosine *Systematic (IUPAC) name (2R,3R,4R,5R)-2-(6-aminopurin-9-yl)- 5-(hydroxymethyl)oxolane-3,4-diol*

Identifiers

CAS number 58-61-7

ATC code C01**EB10**

PubChem 60961

DrugBank APRD00132

Chemical data

Formula $C_{10}H_{13}N_5O_4$

Mol. weight 267.242 g/mol

Adenosine is a nucleoside comprised of adenine attached to a ribose (ribofuranose) moiety via a ^{2}-N9-glycosidic bond.

Adenosine plays an important role in biochemical processes, such as energy transfer - as adenosine triphosphate (ATP) and adenosine diphosphate (ADP) - as well as in signal transduction as cyclic adenosine monophosphate, cAMP.

Pharmacological effects

Anti-inflammatory Properties

Adenosine is a potent anti-inflammatory agent, acting at its four G-protein coupled receptors. Topical treatment of adenosine to foot wounds in diabetes mellitus has been shown in lab animals to drastically increase tissue repair and reconstruction. Topical administration of adenosine for use in wound healing deficiencies and diabetes mellitus in humans is currently under clinical investigation.

Action on the heart

When administered intravenously, adenosine causes transient heart block in the AV node. It also causes endothelial dependent relaxation of smooth muscle as is found inside the artery walls. This causes dilatation of the "normal" segments of arteries where the endothelium is not separated from the tunica media by atherosclerotic plaque. This feature allows physicians to use adenosine to test for blockages in the coronary arteries, by exaggerating the difference between the normal and abnormal segments.

In individuals suspected of suffering from a supraventricular tachycardia (SVT), adenosine is used to help identify the rhythm. Certain SVTs can be successfully terminated with adenosine. This includes any re-entrant arrhythmias that require the AV node for the re-entry (e.g., AV reentrant tachycardia (AVRT), AV nodal reentrant tachycardia (AVNRT). In addition, atrial tachycardia can sometimes be terminated with adenosine.

Adenosine has a direct effect on atrial tissue causing a shortening of the refractory period. When administered via a central lumen catheter, adenosine has been shown to initiate atrial fibrillation because of its affect on atrial tissue. In individuals with accessory pathways, the onset of atrial fibrillation can lead to a life threatening ventricular fibrillation.

Fast rhythms of the heart that are confined to the atria (e.g., atrial fibrillation, atrial flutter) or ventricles (e.g., monomorphic ventricular tachycardia) and do not involve the AV node as part of the re-entrant circuit are not typically affected by adenosine.

Because of the effects of adenosine on AV node-dependent SVTs, adenosine is considered a class V antiarrhythmic agent.

The pharmacological effects of adenosine are blunted in individuals who are taking methylxanthines (e.g., caffeine (found in coffee) and theophylline (found predominantly in tea)).

Dosage

When given for the evaluation or treatment of an SVT, the initial dose is 6 mg, given as a fast IV push. Due to adenosine's extremely short half-life, start the IV line as proximal to the

heart as possible, such as the antecubital fossa. If this has no effect (e.g., no evidence of transient AV block), a 12mg dose can be given 1-2 minutes after the first dose. If the 12mg dose has no effect, a second 12mg dose can be administered 1-2 minutes after the previous dose. Some clinicians may prefer to administer a higher dose (typically 18 mg), rather than repeat a dose that apparently had no effect. When given to dilate the arteries, such as in a "stress test", the dosage is typically 0.14 mg/kg/min, administered for 4 or 6 minutes, depending on the protocol.

Consider increasing the recommended dose in patients on theophylline since methylxanthines prevent binding of adenosine at receptor sites. Consider decreasing the dose in patients on dipyridamole (Persantine) and diazepam (Valium) because adenosine potentiates the effects of these drugs.

Consider decreasing the recommended dose in half in patients who are presenting Congestive Heart Failure, Myocardial Infarction, shock, hypoxia, and/or hepatic or renal insufficiency.

Consider decreasing the recommended dose in half for elderly patients.

Drug Interactions

beta blockers and dopamine may precipitate toxicity in the patient.

Contraindications

Poison/Drug induced tachycardia, Asthma (relative contraindication), 2nd or 3rd degree heart block, Atrial fibrillation, atrial flutter, Ventricular tachycardia, Sick sinus syndrome, Stokes-Adams Attack, Wolf-Parkinson-White syndrome, bradycardia with Premature Ventricular Contractions (PVCs).

Side effects

Many individuals experience facial flushing, lightheadedness, diaphoresis, or nausea after administration of adenosine. These symptoms are transitory, usually lasting less than one minute.

Metabolism

When adenosine enters the circulation, it is broken down by adenosine deaminase, which is present in red cells and the vessel wall.

Dipyridamole, an inhibitor of adenosine deaminase, allows adenosine to accumulate in the blood stream. This causes an increase in coronary vasodilatation.

Routes oral or intravenous

Amiodarone belongs to a class of drugs called Vaughan-Williams Class III antiarrhythmic agent. It is used in the treatment of a wide range of cardiac tachyarhthmias, including both ventricular and supraventricular (atrial) arrhythmias.

History

Amiodarone was initially developed in 1961 in Belgium as a treatment for angina. It was widely used throughout Europe as an anti-anginal medication, and was soon found to suppress arrhythmias.

Dr. Bramah Singh determined that amiodarone and sotalol belonged to a new class of antiarrhythmic agents (what would become the class III antiarrhythmic agents) that would prolong repolarization of the cardiac action potential. Based on this, the Argentinian physician Dr. Mauricio Rosenbaum began using amiodarone to treat his patients who suffered from supraventricular and ventricular arrhythmias, with impressive results. Based on papers written by Dr. Rosenbaum, physicians in the United States began prescribing amiodarone to their patients with potentially life-threatening arrhythmias in the late 1970s. By that time, amiodarone was commonly prescribed throughout Europe for the treatment of arrhythmias. Because amiodarone was not approved by the Food and Drug Administration for use in the United States at the time, physicians were forced to directly obtain amiodarone from pharmaceutical companies in Canada and Europe.

The FDA was reluctant to officially approve the use of amiodarone, since initial reports had shown increased incidence of serious pulmonary side-effects of the drug. In the mid 1980s, the European pharmaceutical companies began putting pressure on the FDA to approve amiodarone by threatening to cut the supply to the American physicians if it was not approved. In December of 1985, amiodarone was approved by the FDA for the treatment of arrhythmias. This makes amiodarone one of the few drugs approved by the FDA without rigorous randomized clinical trials.

Dosing

Amiodarone is available in oral and intravenous formulations.

Orally, it is available under the trade names *Pacerone®* (produced by Upsher-Smith Laboratories, Inc.) and *Cordarone®* (produced by Wyeth-Ayerst Laboratories) in 200mg and 400mg tablets; It is also available under the trade name *Aratac®* in 100mg and 200mg tablets in Australia and New Zealand.

It is also available in intravenous ampules and vials, typically in 150mg increments.

The dose of amiodarone administered is tailored to the individual and the dysrhythmia that is being treated. When administered orally, the bioavailability of amiodarone is quite variable. Absorption ranges from 22 to 95%, with better absorption when it is given with food.[1]

Amiodarone is fat-soluble, and tends to concentrate in tissues including fat, muscle, liver, lungs, and skin. This confers a high volume of distribution (5000 liters in a 70kg adult) and a long half-life. Due to the long half-life of amiodarone, oral loading typically takes days to weeks.

An oral loading dose is typically a total of 10 grams, divided over one to two weeks. Once an individual is loaded, a typical maintenance dose of amiodarone is 100 or 200 mg either once or twice daily.

An intravenous loading dose is typically 300mg in 20-30cc D5W for cardiac arrest. The loading infusion for dysrhythmias is typically 150mg in a 100cc bag of D5W given over 10 minutes. Both can be followed by a 360mg slow infusion over 6 hours then a maintenance infusion of 540mg over 18 hours.

Mechanism of action

Amiodarone is categorized as a class III antiarrhythmic agent, and prolongs phase 3 of the cardiac action potential. It has numerous other effects however, including actions that are similar to those of antiarrhythmic classes Ia, II, and IV.

Amiodarone shows beta blocker-like and calcium channel blocker-like actions on the SA and AV nodes, increases the refractory period via sodium- and potassium-channel effects, and slows intra-cardiac conduction of the cardiac action potential, via sodium-channel effects.

Indications for use

Because amiodarone has a low incidence of pro-arrhythmic effects, it has been used both in the treatment of acute life-threatening arrhythmias as well as the chronic suppression of arrhythmias. It is useful both in supraventricular arrhythmias and ventricular arrhythmias.

Ventricular fibrillation

The treatment of choice for ventricular fibrillation (VF) is electrical defibrillation. However amiodarone can be useful in shock-refractory VF. In the ARREST trial, amiodarone was shown to improve survival to hospital admission (when compared to placebo) in individuals who suffer cardiac arrest with shock-refractory VF.[2] It is on the basis of this study that the guidelines created by the American Heart Association for the treatment of VF include amiodarone as a second line agent (after epinephrine or vasopressin). ARREST was not adequately powered to demonstrate survival to hospital discharge.

Ventricular tachycardia

Amiodarone may be used in the treatment of ventricular tachycardia in certain instances. Individuals with hemodynamically unstable ventricular tachycardia should not initially receive amiodarone. These individuals should be defibrillated out of their unstable rhythm.

Amiodarone can be used in individuals with hemodynamically stable ventricular tachycardia. In these cases, amiodarone can be used regardless of the individual's underlying heart function and the type of ventricular tachycardia; it can be used in individuals with monomorphic ventricular tachycardia as well as individuals with polymorphic ventricular tachycardia. The dose of amiodarone is 150 mg IV administered over 10 minutes.

Atrial fibrillation

Individuals who have undergone open heart surgery are at an increased risk of developing atrial fibrillation (or AF) in the first few days post-procedure. In the ARCH trial, intravenous amiodarone (2 grams administered over 2 days) has been shown to reduce the incidence of atrial fibrillation after open heart surgery when compared to placebo.[3] However, clinical studies have failed to demonstrate long-term efficacy and have shown potentially fatal side effects such as pulmonary toxicities. While Amiodarone is not approved for AF by the FDA, it is a commonly prescribed off-label treatment due to the lack of efficacious treatment alternatives.

Contraindications

The only absolute contraindications to the administration of amiodarone is allergic reaction (ie: anaphylaxis) to the compound. However, because of the wide spectrum of the mechanism of action of amiodarone and the numerous side effects possible, there are a number of groups for which care should be taken when administering the drug.

Individuals who are pregnant or may become pregnant are strongly advised to not take amiodarone. Since amiodarone can be expressed in breast milk, women taking amiodarone are advised to stop nursing.

It is contraindicated in individuals with sinus nodal bradycardia, atrioventricular block, and second or third degree heart block who do not have an artificial pacemaker.

Individuals with baseline depressed lung function should be monitored closely if amiodarone therapy is to be initiated.

The injection should not be given to neonates, because the benzyl alcohol it contains may cause the fatal "gasping syndrome".

Metabolism

Amiodarone is extensively metabolized in the liver, and can affect the metabolism of numerous other drugs. The major metabolite of amiodarone is desethylamiodarone (DEA), which also has antiarrhythmic properties. The metabolism of amiodarone is inhibited by grapefruit juice, leading to elevated serum levels of amiodarone.

Interactions with other drugs

The pharmacokinetics of numerous drugs, including many that are commonly administered to individuals with heart disease, are affected by amiodarone. Particularly, doses of digoxin should be halved in individuals taking amiodarone.

Amiodarone potentiates the action of warfarin. Individuals taking both of these medications should have their warfarin dose halved and their anticoagulation status (measured as prothrombin time (PT) and international normalized ratio (INR)) measured more frequently. The effect of amiodarone in the warfarin concentration can be as early as a few days after initiation of treatment, or can be delayed a few weeks.

Amiodarone inhibits the action of the cytochrome P450 isozyme family. This reduces the clearance of many drugs, including the following: -

- Ciclosporin
- Digoxin
- Flecainide
Procainamide
Quinidine
- Sildenafil
- Simvastatin
- Theophylline
- Warfarin

Excretion

Unlike most other drugs, which are excreted via the urine or feces, amiodarone is excreted via shedding of epithelial cells. This includes loss of skin cells and loss of the cells of the lining of the gastrointestinal system. While the human body sheds millions of cells a day, the amount of amiodarone lost per day is small, giving a long half life (13 to 103 days). Therefore, if an individual was taking amiodarone on a chronic basis, if it is stopped it will remain in the system for months.

Side effects

Amiodarone has numerous side effects. Most individuals administered amiodarone on a chronic basis will experience at least one side effect.

Thyroid

Due to the iodine content of the agent (37.3% by weight), abnormalities in thyroid function are common. Amiodarone is structurally similar to thyroxine (a thyroid hormone), which contributes to the effects of amiodarone on thyroid function. The incidence of hypothyroidism is about 6%, while the incidence of hyperthyroidism is about 2%. They are called Wolff-Chaikoff effect and Jodbasedow effect separately.

Measurement of free thyroxine (FT4) alone may be unreliable and thyroid-stimulating hormone (TSH) should therefore also be checked every 6 months [4].

Thyroid uptake measurements (I-123 or I-131), which are used to differentiate causes of hyperthyroidism, are generally unreliable in patients who have been taking amiodarone. Because of the high iodine content of amiodarone, the thyroid gland is effectively saturated, thus preventing further uptake of isotopes of iodine.

Eye

Corneal micro-deposits (Corneal verticillata, also called vortex keratopathy) are almost universally present (over 90%) in individuals taking amiodarone for at least 6 months. These deposits typically do not cause any symptoms. About 1 in 10 individuals may complain of a blueish halo. Optic neuropathy occurs in 1-2% of people and is not dosage dependent. Bilateral optic disk swelling and mild and reversible visual field defects can also occur.

Gastrointestinal system

Liver toxicity due to amiodarone is quite rare. A drug-induced hepatitis (inflammation of the liver) may occur and is sometimes reversible by lowering the dose.

Skin

Long-term administration of amiodarone is associated with a blue-grey discoloration of the skin, "smurf syndrome." This is more commonly seen in individuals with lighter skin tones. The discoloration may revert upon cessation of the drug. However, the skin color may not return completely to normal.

Individuals taking amiodarone may become more sensitive to the harmful effects of UV-A light. Taking sunblock that also blocks UV-A rays appears to prevent this side effect.

Lung

The most serious reaction that is due to amiodarone is idiopathic pulmonary fibrosis. The incidence of pulmonary fibrosis is not dose related. Some individuals were noted to develop pulmonary fibrosis after a week of treatment, while others did not develop it after years of continuous use. There are no known factors that increase the incidence of amiodarone-induced pulmonary fibrosis in a particular individual. Common practice is to avoid the agent if possible in individuals with decreased lung function.

The most specific test of pulmonary toxicity due to amiodarone is a dramatically decreased DLCO noted on pulmonary function testing.

Asthma is a disease of the respiratory system in which the airways constrict, become inflamed, and are lined with excessive amounts of mucus, often in response to one or more "triggers," such as exposure to an environmental stimulant (or allergen), cold air, exercise, or emotional stress. In children, the most common triggers are viral illnesses such as those that cause the common cold.[1] This airway narrowing causes symptoms such as wheezing, shortness of breath, chest tightness, and coughing, which respond to bronchodilators. Between episodes, most patients feel fine.

The disorder is a chronic or recurring inflammatory condition in which the airways develop increased responsiveness to various stimuli, characterized by bronchial hyper-responsiveness, inflammation, increased mucus production, and intermittent airway obstruction. The symptoms of asthma, which can range from mild to life threatening, can usually be controlled with a combination of drugs and enviromental changes.

Public attention in the developed world has recently focused on asthma because of its rapidly increasing prevalence, affecting up to one in four urban children.[2] Susceptibility to asthma can be explained in part by genetic factors, but no clear pattern of inheritance has been found. Asthma is a complex disease that is influenced by multiple genetic, developmental, and environmental factors, which interact to produce the overall condition.

History

The word asthma is derived from the Greek aazein, meaning "sharp breath." The word first appears in Homer's Iliad;[3] Hippocrates was the first to use it in reference to the medical condition. Hippocrates thought that the spasms associated with asthma were more likely to occur in tailors, anglers, and metalworkers. Six centuries later, Galen wrote much about asthma, noting that it was caused by partial or complete bronchial obstruction. Moses Maimonides, an influential medieval rabbi, philosopher, and physician, wrote a treatise on asthma, describing its prevention, diagnosis, and treatment.[4] In the 17th century, Bernardino Ramazzini noted a connection between asthma and organic dust. The use of bronchodilators started in 1901, but it was not until the 1960s that the inflammatory component of asthma was recognized, and anti-inflammatory medications were added to the regimen.

Signs and symptoms

In some individuals asthma is characterized by chronic respiratory impairment. In others it is an intermittent illness marked by episodic symptoms that may result from a number of triggering events, including upper respiratory infection, airborne allergens, and exercise.

An acute exacerbation of asthma is referred to as an asthma attack. The clinical hallmarks of an attack are shortness of breath (dyspnea) and either wheezing or stridor. Although the latter is "often regarded as the sine qua non of asthma,"[5] some victims present primarily with coughing, and in the late stages of an attack, air motion may be so impaired that no wheezing may be heard. When present the cough may sometimes produce clear sputum. The onset may be sudden, with a sense of constriction in the chest, breathing becomes difficult, and wheezing occurs (primarily upon expiration, but can be in both respiratory phases).

Signs of an asthmatic episode or asthma attack are either stridor or wheezing, rapid breathing (tachypnea), prolonged expiration, a rapid heart rate (tachycardia), rhonchous lung sounds (audible through a stethoscope), and over-inflation of the chest. During a serious asthma attack, the accessory muscles of respiration (sternocleidomastoid and scalene muscles of the neck) may be used, shown as in-drawing of tissues between the ribs and above the sternum and clavicles, and the presence of a paradoxical pulse (a pulse that is weaker during inhalation and stronger during exhalation).

During very severe attacks, an asthma sufferer can turn blue from lack of oxygen, and can experience chest pain or even loss of consciousness. Severe asthma attacks may lead to respiratory arrest and death. Despite the severity of symptoms during an asthmatic episode, between attacks an asthmatic may show few signs of the disease.

Diagnosis

In most cases, a physician can diagnose asthma on the basis of typical findings in a patient's clinical history and examination. Asthma is strongly suspected if a patient suffers from eczema or other allergic conditions—suggesting a general atopic constitution—or has a family history of asthma. While measurement of airway function is possible for adults, most new cases are diagnosed in children who are unable to perform such tests. Diagnosis in children is based on a careful compilation and analysis of the patient's medical history and subsequent improvement with an inhaled bronchodilator medication. In adults, diagnosis can be made with a peak flow meter (which tests airway restriction), looking at both the diurnal variation and any reversibility following inhaled bronchodilator medication.

Testing peak flow at rest (or baseline) and after exercise can be helpful, especially in young asthmatics who may experience only exercise-induced asthma. If the diagnosis is in doubt, a more formal lung function test may be conducted. Once a diagnosis of asthma is made, a patient can use peak flow meter testing to monitor the severity of the disease.

Differential diagnosis

Before diagnosing someone as asthmatic, alternative possibilities should be considered. A physician taking a history should check whether the patient is using any known bronchoconstrictors (substances that cause narrowing of the airways, e.g., certain anti-inflammatory agents or beta-blockers).

Chronic obstructive pulmonary disease, which closely resembles asthma, is correlated with more exposure to cigarette smoke, an older patient, less symptom reversibility after bronchodilator administration (as measured by spirometry), and decreased likelihood of family history of atopy.

Pulmonary aspiration, whether direct due to dysphagia (swallowing disorder) or indirect (due to acid reflux), can show similar symptoms to asthma. However, with aspiration, fevers might also indicate aspiration pneumonia. Direct aspiration (dysphagia) can be diagnosed by performing a Modified Barium Swallow test and treated with feeding therapy by a qualified speech therapist. If the aspiration is indirect (from acid reflux) then treatment directed at this is indicated.

Only a minority of asthma sufferers have an identifiable allergy trigger. The majority of these triggers can often be identified from the history; for instance, asthmatics with hay fever or pollen allergy will have seasonal symptoms, those with allergies to pets may experience an abatement of symptoms when away from home, and those with occupational asthma may improve during leave from work. Occasionally, allergy tests are warranted and, if positive, may help in identifying avoidable symptom triggers.

After pulmonary function has been measured, radiological tests, such as a chest X-ray or CT scan, may be required to exclude the possibility of other lung diseases. In some people, asthma may be triggered by gastroesophageal reflux disease, which can be treated with suitable antacids. Very occasionally, specialized tests after inhalation of methacholine — or, even less commonly, histamine — may be performed.

Asthma is categorized by the United States National Heart, Lung and Blood Institute as falling into one of four categories: mild intermittent, mild persistent, moderate persistent and severe persistent. The diagnosis of "severe persistent asthma" occurs when symptoms are continual with frequent exacerbations and frequent nighttime symptoms, result in limited physical activity and when lung function as measured by PEV or FEV1 tests is less than 60% predicted with PEF variability greater than 30%.

There is no cure for asthma. Doctors have only found ways to prevent attacks and relieve the symptoms such as tightness of the chest and trouble breathing.

Pathophysiology

Bronchoconstriction

In essence, asthma is the result of an immune response in the bronchial airways.[6]

The airways of asthmatics are "hypersensitive" to certain triggers, also known as stimuli (see below). In response to exposure to these triggers, the bronchi (large airways) contract into spasm (an "asthma attack"). Inflammation soon follows, leading to a further narrowing of the airways and excessive mucus production, which leads to coughing and other breathing difficulties.

There are several categories of stimuli:

- allergenic air pollution, from nature, typically inhaled, which include waste from common household insects, such as the house dust mite and cockroach, grass pollen, mould spores and pet epithelial cells;
- medications**, including** aspirin[7] **and** ^{2}-adrenergic antagonists **(beta blockers);**
- Use of fossil fuel related allergenic air pollution, such as ozone, Smog, Summer smog, nitrogen dioxide, and sulfur dioxide, which is thought to be one of the major reasons for the high prevalence of asthma in urban areas;
- various industrial compounds and other chemicals, notably sulfites; chlorinated swimming pools generate chloramines—monochloramine (NH_2Cl), dichloramine ($NHCl_2$) and trichloramine (NCl_3)—in the air around them, which are known to induce asthma.[8]
- early childhood infections, especially viral respiratory infections. However, persons of any age can have asthma triggered by colds and other respiratory infections even though their normal stimuli might be from another category (e.g. pollen) and absent at the time of infection. 80% of asthma attacks in adults and 60% in children are caused by respiratory viruses.

- exercise, the effects of which differ somewhat from those of the other triggers;
- (in some countries) - allergenic indoor air pollution from Newsprint & other literature such as, junk mail leaflets & glossy magazines.
- emotional stress which is poorly understood as a trigger. Perhaps because crying might be a form of exercise or because being given an asthma attack may be distressing.

Bronchial inflammation

The mechanisms behind allergic asthma—i.e., asthma resulting from an immune response to inhaled allergens—are the best understood of the causal factors. In both asthmatics and non-asthmatics, inhaled allergens that find their way to the inner airways are ingested by a type of cell known as antigen presenting cells, or APCs. APCs then "present" pieces of the allergen to other immune system cells. In most people, these other immune cells (TH0 cells) "check" and usually ignore the allergen molecules. In asthmatics, however, these cells transform into a different type of cell (TH2), for reasons that are not well understood. The resultant TH2 cells activate an important arm of the immune system, known as the humoral immune system. The humoral immune system produces antibodies against the inhaled allergen. Later, when an asthmatic inhales the same allergen, these antibodies "recognize" it and activate a humoral response. Inflammation results: chemicals are produced that cause the airways to constrict and release more mucus, and the cell-mediated arm of the immune system is activated. The inflammatory response is responsible for the clinical manifestations of an asthma attack. The following section describes this complex series of events in more detail.

Pathogenesis

The fundamental problem in asthma appears to be immunological: young children in the early stages of asthma show signs of excessive inflammation in their airways. Epidemiological findings give clues as to the pathogenesis: the incidence of asthma seems to be increasing worldwide, and asthma is now very much more common in affluent countries.

In 1968 Andor Szentivanyi first described The Beta Adrenergic Theory of Asthma; in which blockage of the Beta-2 receptors of pulmonary smooth muscle cells causes asthma.[9] Szentivanyi's Beta Adrenergic Theory is a citation classic[10] and has been cited more times than any other article in the history of the Journal of Allergy.

In 1995 Szentivanyi and colleagues demonstrated that IgE blocks beta-2 receptors.[11] Since overproduction of IgE is central to all atopic diseases, this was a watershed moment in the world of Allergy.[12]

The Beta-Adrenergic Theory has been cited in the scholarship of such noted investigators as Richard F. Lockey (former President of The American Academy of Allergy, Asthma, and Immunology),[13] Charles Reed (Chief of Allergy at Mayo Medical School),[14] and Craig Venter (Human Genome Project).[15]

One theory of pathogenesis is that asthma is a disease of hygiene. In nature, babies are exposed to bacteria and other antigens soon after birth, "switching on" the TH1 lymphocyte cells of the immune system that deal with bacterial infection. If this stimulus is insufficient—as it may be in modern, clean environments—then TH2 cells predominate, and asthma and other allergic diseases may develop. This "hygiene hypothesis" may explain the increase in asthma in affluent populations. The TH2 lymphocytes and eosinophil cells that protect us against parasites and other infectious agents are the same cells responsible for the allergic reaction. The Charcot-Leyden crystals are formed when the crystalline material in eosinophils coalesce. These crystals are significant in sputum samples of people with asthma. In the developed world, these parasites are now rarely encountered, but the immune response remains and is wrongly triggered in some individuals by certain allergens.

Another theory is based on the correlation of air pollution and the incidence of asthma. Although it is well known that substantial exposures to certain industrial chemicals can cause acute asthmatic episodes, it has not been proven that air pollution is responsible for the development of asthma. In Western Europe, most atmospheric pollutants have fallen significantly over the last 40 years, while the prevalence of asthma has risen.

Finally, it has been postulated that some forms of asthma may be related to infection, in particular by Chlamydia pneumoniae.[16] This issue remains controversial, as the relationship is not borne out by meta-analysis of the research.[17] The correlation seems to be not with the onset, but rather with accelerated loss of lung function in adults with new onset of non-atopic asthma.[18] One possible explanation is that some asthmatics may have altered immune response that facilitates long-term chlamydia pneumonia infection.[19] The response to targeting with macrolide antibiotics has been investigated, but the temporary benefit reported in some studies may reflect just their anti-inflammatory activities rather than their antimicrobic action.[17]

Asthma and sleep apnea

It is recognized with increasing frequency, that patients who have both obstructive sleep apnea (OSA) and bronchial asthma, often improve tremendously when the sleep apnea is diagnosed and treated.[20] CPAP is not effective in patients with nocturnal asthma only.[21]

Asthma and gastro-esophageal reflux disease

If gastro-esophageal reflux disease is present, the patient may have repetitive episodes of acid aspiration, which results in airway inflammation and "irritant-induced" asthma. GERD may be common in difficult-to-control asthma, but generally speaking, treating it does not seem to affect the asthma.[22]

Treatment

The most effective treatment for asthma is identifying triggers, such as pets or aspirin, and limiting or eliminating exposure to them. Desensitization to allergens has been shown to be a treatment option for certain patients.[23]

As is common with respiratory disease, smoking adversely affects asthmatics in several ways, including an increased severity of symptoms, a more rapid decline of lung function, and decreased response to preventive medications.[24] Asthmatics who smoke typically require additional medications to help control their disease. Furthermore, exposure of both nonsmokers and smokers to secondhand smoke is detrimental, resulting in more severe asthma, more emergency room visits, and more asthma-related hospital admissions.[25] Smoking cessation and avoidance of secondhand smoke is strongly encouraged in asthmatics.[26]

The specific medical treatment recommended to patients with asthma depends on the severity of their illness and the frequency of their symptoms. Specific treatments for asthma are broadly classified as relievers, preventers and emergency treatment. The Expert panel report 2: Guidelines for the diagnosis and management of asthma (EPR-2)[26] of the U.S. National Asthma Education and Prevention Program, and the British guideline on the management of asthma[27] are broadly used and supported by many doctors. Bronchodilators are recommended for short-term relief in all patients. For those who experience occasional attacks, no other medication is needed. For those with mild persistent disease (more than two attacks a week), low-dose inhaled glucocorticoids or alternatively, an oral leukotriene modifier, a mast-cell stabilizer, or theophylline may be administered. For those who suffer daily attacks, a higher dose of glucocorticoid in conjunction with a long-acting inhaled ^{2}-2 agonist may be prescribed; alternatively, a leukotriene modifier or theophylline may substitute for the ^{2}-2 agonist. In severe asthmatics, oral glucocorticoids may be added to these treatments during severe attacks.

For those in whom exercise can trigger an asthma attack (exercise-induced asthma), higher levels of ventilation and cold, dry air tend to exacerbate attacks. For this reason, activities in which a patient breathes large amounts of cold air, such as skiing and running, tend to be worse for asthmatics, whereas swimming in an indoor, heated pool, with warm, humid air, is less likely to provoke a response.[5]

Researchers at Harvard Medical School (HMS) have come up with convincing evidence that the answer to what causes asthma lies in a special type of natural "killer" cell. This finding means that physicians may not be treating asthma sufferers with the right kinds of drugs. For example, natural killer T cells seem to be resistant to the corticosteroids in widely used inhalers.[28]

Relief medication

Symptomatic control of episodes of wheezing and shortness of breath is generally achieved with fast-acting bronchodilators. These are typically provided in pocket-sized, metered-dose inhalers (MDIs). In young sufferers, who may have difficulty with the coordination necessary to use inhalers, or those with a poor ability to hold their breath for 10 seconds after inhaler use (generally the elderly), an asthma spacer (see top image) is used. The spacer is a plastic cylinder that mixes the medication with air in a simple tube, making it easier for patients to receive a full dose of the drug and allows for the active agent to be dispersed into smaller, more fully inhaled bits. A nebulizer—which provides a larger, continuous dose—can also be used. Nebulizers work by vaporizing a dose of medication in a

saline solution into a steady stream of foggy vapour, which the patient inhales continuously until the full dosage is administered. There is no clear evidence, however, that they are more effective than inhalers used with a spacer. Nebulizers may be helpful to some patients experiencing a severe attack. Such patients may not be able to inhale deeply, so regular inhalers may not deliver medication deeply into the lungs, even on repeated attempts. Since a nebulizer delivers the medication continuously, it is thought that the first few inhalations may relax the airways enough to allow the following inhalations to draw in more medication.

Relievers include:

- Short-acting, selective beta2-adrenoceptor agonists, such as salbutamol (albuterol USAN), levalbuterol, terbutaline and bitolterol. Tremors, the major side effect, have been greatly reduced by inhaled delivery, which allows the drug to target the lungs specifically; oral and injected medications are delivered throughout the body. There may also be cardiac side effects at higher doses (due to Beta-1 agonist activity), such as elevated heart rate or blood pressure; with the advent of selective agents, these side effects have become less common. Patients must be cautioned against using these medicines too frequently, as with such use their efficacy may decline, producing desensitization resulting in an exacerbation of symptoms which may lead to refractory asthma and death.
- Older, less selective adrenergic agonists, such as inhaled [29][30] When used solely as a relief medication, inhaled epinephrine has been shown to be an effective agent to terminate an acute asthmatic exacerbation.[29] In emergencies, these drugs were sometimes administered by injection. Their use via injection has declined due to related adverse effects.
- Anticholinergic medications, such as ipratropium bromide may be used instead. They have no cardiac side effects and thus can be used in patients with heart disease; however, they take up to an hour to achieve their full effect and are not as powerful as the $^{2}\boldsymbol{2}$-adrenoreceptor agonists.

Prevention medication

Current treatment protocols recommend prevention medications such as an inhaled corticosteroid, which helps to suppress inflammation and reduces the swelling of the lining of the airways, in anyone who has frequent (greater than twice a week) need of relievers or who has severe symptoms. If symptoms persist, additional preventive drugs are added until the asthma is controlled. With the proper use of prevention drugs, asthmatics can avoid the complications that result from overuse of relief medications.

Asthmatics sometimes stop taking their preventive medication when they feel fine and have no problems breathing. This often results in further attacks, and no long-term improvement.

Preventive agents include the following.

- Inhaled glucocorticoids (ciclesonide, fluticasone, budesonide, beclomethasone, mometasone, flunisolide, and triamcinolone).
- Leukotriene modifiers (montelukast, zafirlukast, pranlukast, and zileuton).

- Mast cell stabilizers (cromoglicate (cromolyn), and nedocromil).
- Antimuscarinics/anticholinergics (ipratropium, oxitropium, and tiotropium), which have a mixed reliever and preventer effect. (These are rarely used in preventive treatment of asthma, except in patients who do not tolerate beta-2-agonists.)
- Methylxanthines (theophylline and aminophylline), which are sometimes considered if sufficient control cannot be achieved with inhaled glucocorticoids and long-acting ^{2}-agonists alone.
- Antihistamines, often used to treat allergic symptoms that may underlie the chronic inflammation. In more severe cases, hyposensitization ("allergy shots") may be recommended.
- Omalizumab, an IgE blocker; this can help patients with severe allergic asthma that does not respond to other drugs. However, it is expensive and must be injected.
- Methotrexate is occasionally used in some difficult-to-treat patients.
- If chronic acid indigestion (GERD) contributes to a patient's asthma, it should also be treated, because it may prolong the respiratory problem.

Long-acting 22-agonists

Long-acting bronchodilators (LABD) give a 12-hour effect, and are used to give a smoothed symptomatic effect (used morning and night). While patients report improved symptom control, these drugs do not replace the need for routine preventers, and their slow onset means the short-acting dilators may still be required. In November of 2005, the American FDA released a health advisory alerting the public to findings that show the use of Long-acting ^{2}***2***-agonists could lead to a worsening of symptoms, and in some cases death.[31]

Currently available long-acting beta2-adrenoceptor agonists include salmeterol, formoterol, bambuterol, and sustained-release oral albuterol. Combinations of inhaled steroids and long-acting bronchodilators are becoming more widespread; the most common combination currently in use is fluticasone/salmeterol (Advair in the United States, and Seretide in the UK).

A recent meta-analysis of the roles of long-acting beta-agonists may indicate a danger to asthma patients. "These agents can improve symptoms through bronchodilation at the same time as increasing underlying inflammation and bronchial hyper-responsiveness, thus worsening asthma control without any warning of increased symptoms," said Shelley Salpeter in a Cornel study. The study goes on to say that "Three common asthma inhalers containing the drugs salmeterol or formoterol may be causing four out of five U.S. asthma-related deaths per year and should be taken off the market".[32]

Emergency treatment

When an asthma attack is unresponsive to a patient's usual medication, other treatments are available to the physician or hospital:[33]

- oxygen to alleviate the hypoxia (but not the asthma per se) that results from extreme asthma attacks;
- nebulized salbutamol or terbutaline (short-acting beta-2-agonists), often combined with ipratropium (an anticholinergic);
- systemic steroids, oral or intravenous (prednisone, prednisolone, methylprednisolone, dexamethasone, or hydrocortisone)
- other bronchodilators that are occasionally effective when the usual drugs fail:
  - nonspecific beta-agonists, injected or inhaled (epinephrine, isoetharine, isoproterenol, metaproterenol);
  - anticholinergics, IV or nebulized, with systemic effects (glycopyrrolate, atropine);
  - methylxanthines (theophylline, aminophylline);
  - inhalation anesthetics that have a bronchodilatory effect (isoflurane, halothane, enflurane);
  - the dissociative anaesthetic ketamine, often used in endotracheal tube induction
  - magnesium sulfate, intravenous; and
- intubation and mechanical ventilation, for patients in or approaching respiratory arrest.

Alternative and complementary medicine

Many asthmatics, like those who suffer from other chronic disorders, use alternative treatments; surveys show that roughly 50% of asthma patients use some form of unconventional therapy.[34][35] There are little data to support the effectiveness of most of these therapies. A Cochrane systematic review of acupuncture for asthma found no evidence of efficacy.[36] A similar review of air ionisers found no evidence that they improve asthma symptoms or benefit lung function; this applied equally to positive and negative ion generators.[37] A study of "manual therapies" for asthma, including osteopathic, chiropractic, physiotherapeutic and respiratory therapeutic maneuvers, found no evidence to support their use in treating asthma;[38] these manoeuvres include various osteopathic and chiropractic techniques to "increase movement in the rib cage and the spine to try and improve the working of the lungs and circulation"; chest tapping, shaking, vibration, and the use of "postures to help shift and cough up phlegm." On the other hand, one meta-analysis found that homeopathy has a potentially mild benefit in reducing symptom intensity;[39] however, the number of patients involved in the analysis was small, and subsequent studies have not supported this finding.[40] Several small trials have suggested some benefit from various yoga practices, ranging from integrated yoga programs[41] —"yogasanas, Pranayama, meditation, and kriyas"—to sahaja yoga,[42] a form of meditation.

The Buteyko method, a Russian therapy based on breathing exercises, has been investigated with mixed degrees of effect shown. A randomized, controlled trial of just 39 patients in 1998, suggested that it may moderately reduce the need for beta-agonists among asthmatics, but found no objective improvement in lung function.[43] Whilst a trial in New

Zealand, 2003, showed reduced beta-agonist medication by 94% and inhaled steroid by 34% after just six weeks.[44]

Given that some research has identified a negative association between helminth infection (hookworm) and asthma and hay fever, some have suggested that hookworm infestation, although not medically sanctioned, would cure asthma. There is anectdotal evidence to support this.[45]

Prognosis

The prognosis for asthmatics is good, especially for children with mild disease. For asthmatics diagnosed during childhood, 54% will no longer carry the diagnosis after a decade. The extent of permanent lung damage in asthmatics is unclear. Airway remodelling is observed, but it is unknown whether these represent harmful or beneficial changes.[6] Although conclusions from studies are mixed, most studies show that early treatment with glucocorticoids prevents or ameliorates decline in lung function as measured by several parameters.[46] For those who continue to suffer from mild symptoms, corticosteroids can help most to live their lives with few disabilities. The mortality rate for asthma is low, with around 6000 deaths per year in a population of some 10 million patients in the United States.[5] Better control of the condition may help prevent some of these deaths.

Epidemiology

More than 6% of children in the United States have been diagnosed with asthma, a 75% increase in recent decades. The rate soars to 40% among some populations of urban children. Asthma is usually diagnosed in childhood. The risk factors for asthma include:

- a personal or family history of asthma or atopy;

triggers (see Pathophysiology above);
premature birth or low birth weight;
viral respiratory infection in early childhood;
maternal smoking;
being male, for asthma in prepubertal children; and
being female, for persistence of asthma into adulthood.

There is a reduced occurrence of asthma in people who were breast-fed as babies. Current research suggests that the prevalence of childhood asthma has been increasing. According to the Centers for Disease Control and Prevention's National Health Interview Surveys, some 9% of US children below 18 years of age had asthma in 2001, compared with just 3.6% in 1980 (see figure). The World Health Organization (WHO) reports that some 8% of the Swiss population suffers from asthma today, compared with just 2% some 25–30 years ago.[47] Although asthma is more common in affluent countries, it is by no means a problem restricted to the affluent; the WHO estimate that there are between 15 and 20 million asthmatics in India. In the U.S., urban residents, Hispanics, and African Americans are affected more than the population as a whole. Globally, asthma is responsible for around 180,000 deaths annually.[47]

On the remote South Atlantic island Tristan da Cunha, 50% of the population are asthmatics due to heredity transmission of a mutation in the gene CC16.

Socioeconomic factors

The incidence of asthma is higher among low-income populations within a society (even though it is more common in developed countries than developing countries), which in the western world are disproportionately minority, and more likely to live near industrial areas. Additionally, asthma has been strongly associated with the presence of cockroaches in living quarters, which is more likely in such neighbourhoods.[48]

The quality of asthma treatment varies along racial lines, likely because many low-income people cannot afford health insurance and because there is still a correlation between class and race. For example, black Americans are less likely to receive outpatient treatment for asthma despite having a higher prevalence of the disease. They are much more likely to have emergency room visits or hospitalization for asthma, and are three times as likely to die from an asthma attack compared to whites. The prevalence of "severe persistent" asthma is also greater in low-income communities compared with communities with better access to treatment.[49][50]

Asthma and athletics

Asthma appears to be more prevalent in athletes than in the general population. One survey of participants in the 1996 Summer Olympic Games showed that 15% had been diagnosed with asthma, and that 10% were on asthma medication.[51] These statistics have been questioned on at least two bases. Persons with mild asthma may be more likely to be diagnosed with the condition than others because even subtle symptoms may interfere with their performance and lead to pursuit of a diagnosis. It has also been suggested that some professional athletes who do not suffer from asthma claim to do so in order to obtain special permits to use certain performance-enhancing drugs.

There appears to be a relatively high incidence of asthma in sports such as cycling, mountain biking, and long-distance running, and a relatively lower incidence in weightlifting and diving. It is unclear how much of these disparities are from the effects of training in the sport, and from self-selection of sports that may appear to minimize the triggering of asthma.[51][52]

In addition, there exists a variant of asthma called exercise-induced asthma that shares many features with allergic asthma. It may occur either independently, or concurrent with the latter. Exercise studies may be helpful in diagnosing and assessing this condition.

Bronchodilators

A *bronchodilator* is a medication intended to improve bronchial airflow. Treatment of bronchial asthma is the most common application of these drugs. They are also intended to help expand the airways and improve the breathing capacity of patients with emphysema, pneumonia and bronchitis. Pharmaceutically bronchodilators belong to ^{2}2 mimetics - they act on ^{2}2 receptors in bronchial smooth muscle and bronchial mucous membranes. Bronchodilators, particularly non-prescription ones, are often misused as stimulants. A common side effect of these medications is desensitization, which may produce refractory bronchospasm.

Bronchodilators are either short acting or long acting. Short-acting medications provide quick or "rescue" relief from acute bronchoconstriction. Long-acting bronchodilators help to control and prevent symptoms. The three types of prescription bronchodilating drugs are ^{2}2-agonists (short and long acting), anticholinergics (short acting), and theophylline (long acting). Also, cannabis has been shown to be significantly bronchodilating.**[1]**

Short-acting ^{2}2-agonists These are quick-relief or "rescue" medications that provide fast, temporary relief from asthma symptoms or flare-ups. These medications usually take effect within 20 minutes or less, and can last from four to six hours. These inhaled medications are best for treating sudden and severe or new asthma symptoms. Taken 15 to 20 minutes ahead of time, these medications can also prevent asthma symptoms triggered by exercise or exposure to cold air. Patients who regularly or frequently need to take short-acting ^{2}2-agonists should consult their doctor, as such usage indicates uncontrolled asthma, and their routine medications may need adjustment.

Long-acting ^{2}2-agonists These are long-term medications taken routinely in order to control and prevent bronchoconstriction. They are not intended for fast relief. These medications take longer to begin working, but relieve airway constriction for up to 12 hours.

- Inhaled - Commonly taken twice a day with an anti-inflammatory medication, they maintain open airways and prevent asthma symptoms, particularly at night.
- Oral - Long-acting albuterol is available in pill or syrup form.

Effective for 12 hours, albuterol is particularly helpful for nighttime asthma symptoms. Because this medication requires high dosing, there tend to be increased side effects. Therefore it is not commonly prescribed. Side effects include increased heart rate,

hyperactivity, feeling nervous, shaky, or over-excited, and very rarely, upset stomach or difficulty sleeping.

Anticholinergics Only available as an inhalant, ipratropium bromide relieves acute or new asthma symptoms. Because it has no effect on asthma symptoms when used alone, it is most often paired with a short-acting ^{2}2-agonist.While it is considered a relief or rescue medication, it can take a full hour to begin working. For this reason it plays a minor role in asthma treatment. Dry throat is the most common side effect. If the medication gets in contact with the eyes, it may cause blurred vision for a brief time.

Theophylline Available in oral and injectible form, theophylline is a long-acting bronchodilator that prevents asthma episodes.It is prescribed in severe cases of asthma or those that are difficult to control. It must be taken daily and doses cannot be missed. Blood tests are required to monitor therapy and to indicate when dosage adjustment is necessary.Side effects can include nausea, vomiting, diarrhea, stomach or headache, rapid or irregular heart beat, muscle cramps, nervous or jittery feelings, and hyperactivity. These symptoms may signal the need for an adjustment in your medication.It may promote acid reflux, also known as GERD, by relaxing the lower esophageal sphincter muscle. Some medications, such as seizure and ulcer medications and antibiotics containing erythromycin, can interfere with the way theopylline works. Coffee, tea, colas, cigarette smoking, and viral illnesses can all affect the action of theopylline and change it effectiveness. Communicate any change related to these factors to your doctor so that the dose can be altered to fit the new conditions.

Epinephrine (INN) (IPA: [Ì[pjÈn[frYn]) or *adrenaline* (BAN) (IPA: [YÈdr[nYlYn]), sometimes spelled "epinephrin" or "adrenalin" respectively, is a hormone. Epinephrine is a catecholamine, a sympathomimetic monoamine derived from the amino acids phenylalanine and tyrosine. The Latin roots ad-+renes and the Greek roots epi-+nephros both literally mean "on/to the kidney" (referring to the adrenal gland, which secretes epinephrine). Epinephrine is sometimes shortened to *epi* in medical jargon. Epinephrine is now also used in EpiPens. EpiPens are long narrow auto-injectors that administer epinephrine.

In May 1886, William Bates reported the discovery of a substance produced by the adrenal gland in the New York Medical Journal. Epinephrine was isolated and identified in 1895 by Napoleon Cybulski, a Polish physiologist. The discovery was repeated in 1897 by John Jacob Abel. Jokichi Takamine discovered the same hormone in 1900, without knowing about the previous discovery. It was first artificially synthesized in 1904 by Friedrich Stolz.

Actions in the body

Epinephrine plays a central role in the short-term stress reaction—the physiological response to threatening, exciting or environmental stressor conditions such as high noise levels or bright light (see Fight-or-flight response). It is secreted by the adrenal medulla. When released into the bloodstream, epinephrine binds to multiple receptors and has numerous effects throughout the body. It increases heart rate and stroke volume, dilates the pupils, and constricts arterioles in the skin and gut while dilating arterioles in leg muscles. It elevates the blood sugar level by increasing depolymerization of glycogen to glucose in the

liver, and at the same time begins the breakdown of lipids in adipocytes. Epinephrine has a suppressive effect on the immune system.

Epinephrine is used as a drug to promote peripheral vascular resistance via alpha-stimulated vasoconstriction in cardiac arrest and other cardiac dysrhythmias resulting in diminished or absent cardiac output, such that blood is shunted to the body's core. This beneficial action comes with a significant negative consequence—increased cardiac irritability—which may lead to additional complications immediately following an otherwise successful resuscitation. Alternatives to this treatment include vasopressin, a powerful antidiuretic which also increases peripheral vascular resistance leading to blood shunting via vasoconstriction, but without the attendant increase to myocardial irritability.

Because of its suppressive effect on the immune system, epinephrine is used to treat anaphylaxis and sepsis. Allergy patients undergoing immunotherapy may receive an epinephrine rinse before the allergen extract is administered, thus reducing the immune response to the administered allergen. It is also used as a bronchodilator for asthma if specific beta2-adrenergic receptor agonists are unavailable or ineffective. Adverse reactions to epinephrine include palpitations, tachycardia, anxiety, headache, tremor, hypertension, and acute pulmonary edema.

A pheochromocytoma is a tumor of the adrenal gland (or, rarely, the ganglia of the sympathetic nervous system), which secretes excessive amounts of catecholamines, usually epinephrine.

Pharmacology

Epinephrine's actions are mediated through adrenergic receptors (sometimes referred to as adrenoceptors).

It binds to ±***1*** receptors of liver cells, which activate inositol-phospholipid signaling pathway, signaling the phosphorylation of insulin, leading to reduced ability of insulin to bind to its receptors.

Epinephrine also activates ^{2}-adrenergic receptors of the liver and muscle cells, thereby activating the adenylate cyclase signaling pathway, which will in turn increase glycogenolysis. ^{2}2 receptors are found primarily in skeletal muscle blood vessels where they do indeed trigger vasodilation. However Alpha receptors are found in most smooth muscles and splanchnic vessels, and epinephrine triggers vasoconstriction in those vessels. Thus, depending on the patient, administration of epinephrine may raise or lower blood pressure, depending whether or not the net increase or decrease in peripheral resistance can balance the positive inotropic and chronotropic effects of epinephrine on the heart.

Terminology

Although widely referred to as "adrenaline" outside of the US, and the lay public worldwide, the USAN and INN for this chemical is "epinephrine" because "adrenaline" bore too much similarity to the Parke, Davis & Co trademark "adrenalin" (without the "e") which was registered in the US.

The BAN and EP term for this chemical is "adrenaline", and is indeed now one of the few differences between the INN and BAN systems of names.

Amongst US health professionals the term epinephrine is generally used over adrenaline. However, it should be noted that when referring to pharmaceuticals that mimic the actions of epinephrine/adrenaline their receptor sites are universally referred to as "adrenergics".

Epinephrine also known as adrenaline can be found in nature in the R form; however, racemic mixtures of the molecule can be used if its chirality is destroyed.

Routes Oral, inhalational, IV

Salbutamol (INN) or *albuterol* (USAN) is a short-acting ²2-adrenergic receptor agonist used for the relief of bronchospasm in conditions such as asthma and COPD.

Salbutamol sulfate is usually given by the inhaled route for direct effect on bronchial smooth muscle. This is usually achieved through a metered dose inhaler (MDI), nebuliser or other proprietary delivery devices (e.g. Rotahaler or Autohaler). Salbutamol can also be given orally or intravenously. However, some asthmatics may not respond to these medications as they will not have the required DNA base sequence in a specific gene.

Salbutamol became available in the United Kingdom in 1969 and in the United States in 1980 under the trade name *Ventolin*.

Clinical use

Salbutamol is specifically indicated in the following conditions:

- acute asthma
- symptom relief during maintenance therapy of asthma and other conditions with reversible airways obstruction (including COPD)
- protection against exercise-induced asthma
- hyperkalemia, especially in patients with renal failure
- can be aerosolized for patients with Cystic Fibrosis, along with ipratropium bromide and pulmozyme.

As a ^{2}***2***-agonist, salbutamol also finds use in obstetrics. Intravenous salbutamol can be used as a tocolytic to relax the uterine smooth muscle to delay premature labour. Whilst preferred over agents such as atosiban and ritodrine, its role has largely been replaced by the calcium-channel blocker nifedipine which is more effective, better tolerated and orally administered. (Rossi, 2004)

Mode of action

As with other ^{2}***2***-adrenergic receptor agonists, salbutamol binds to ^{2}***2***-adrenergic receptors with a higher affinity than ^{2}***1***-receptors. In the airway, activation of ^{2}2-receptors results in relaxation of bronchial smooth muscle resulting in a widening of the airway (bronchodilation). Inhaled salbutamol sulfate has a rapid onset of action, providing relief within 5-15 minutes of administration.

In tocolysis, the activation of ^{2}***2***-receptors results in relaxation of uterine smooth muscle, thus delaying labour.

Adverse effects

Whilst salbutamol is well-tolerated, particularly when compared with previous therapies such as theophylline, like all medications there exists the potential for adverse drug reactions to occur - especially when in high doses, or when taken orally or intravenously.

Common adverse effects include: tremor, palpitations and headache. (Rossi, 2004)

Infrequent adverse effects include: tachycardia, muscle cramps, agitation, hypokalemia, hyperactivity in children, and insomnia. (Rossi, 2004)

Other brand names

Salbutamol is sold under the brand names *Airomir*, *Asthalin*, *Asmol*, *Buventol*, *Proventil*, *Salamol*, *Sultanol*, *Ventolin* and *Volmax*.

Legal status $P_{(UK)}$

Routes oral, IV

Theophylline is a methylxanthine drug used in therapy for respiratory diseases such as COPD or asthma under a variety of brand names. As a member of the xanthine family, it bears structural and pharmacological similarity to caffeine. It is naturally found in black tea and green tea.

The main actions of theophylline are:

- relaxing of bronchial smooth muscle

positive inotropic (increasing heart muscle contractility and efficiency)
positive chronotropic (increasing heart rate)
increase of blood pressure
increase of renal blood flow
some anti-inflammatory effects

History

Theophylline was first extracted from tea leaves around 1888 by the German biologist Albrecht Kossel. The drug was chemically identified in 1896 and eventually it was synthesized by another German scientist, Wilhelm Traube. Theophylline's first clinical use in asthma came in the 1950s.

Side effects

The use of theophylline is complicated by the fact that it interacts with various drugs, chiefly cimetidine and phenytoin, and that it has a narrow therapeutic index, so its use must be monitored to avoid toxicity. It can also cause nausea, diarrhea, increase in heart rate, arrhythmias and CNS excitation. Its toxicity is increased by erythromycin, cimetidine and fluoroquinolones.

The main therapeutic uses of theophylline are:

- chronic obstructive diseases of the airways
- chronic obstructive pulmonary disease (COPD)
- bronchial asthma.

A proposed mechanism of action includes a non-specific inhibition of phosphodiesterase enzymes, producing an increase in intracellular cyclic AMP; however, this is not known with certainty.[1][2][3]

Theophylline has been shown to inhibit TGF-beta mediated conversion of pulmonary fibroblasts into myofibroblasts in COPD and asthma via cAMP-PKA pathway and suppresses COL1 mRNA which codes for the protein collagen. (Yano, Biochem and Biophys Res Comm V341-3, 2006)

It has been shown that theophylline may reverse the clinical observations of steroid insensitivity in patients with COPD and asthmatics who are active smokers (a condition resulting in oxidative stress) via a distinctly separate mechanism. Theophylline in vitro can restore the reduced HDAC (histone deacetylase) activity that is induced by oxidative stress (i.e. in smokers), returning steroid responsiveness toward normal (Ito et al., 2002a).

Furthermore, theophylline has been shown to directly activate HDAC2 (Ito et al., 2002b). (Corticosteroids switch off the inflammatory response by blocking the expression of inflammatory mediators through deacetylation of histones, an effect mediated via histone deacetylase-2 (HDAC2). Once deacetylated, DNA is rewound around histones and repackaged so that the promoter regions of inflammatory genes are unavailable for binding of transcription factors such as NFkB that act to turn on inflammatory activity. It has recently been shown that the oxidative stress associated with cigarette smoke can inhibit the activity of HDAC2, thereby blocking the anti-inflammatory effects of corticosteroids.) Thus theophylline could prove to be a novel form of adjunct therapy in improving the clinical response to steroids in smoking asthmatics.

Mast cell stabilizers

Mast cell stabilizers are medications used to prevent or control certain allergic disorders. They block a calcium channel essential for mast cell degranulation, stabilizing the cell and so prevent the release of histamine and related mediators.

As inhalers thay are used to treat asthma, as nasal sprays to treat Hay fever (allergic rhinitis) and as eye drops for allergic conjunctivitis. Finally in oral form they are used to treat the rare condition of mastocytosis.

Anticholinergics

An *anticholinergic* agent is a member of a class of pharmaceutical compounds which serve to reduce the effects mediated by acetylcholine in the central nervous system and peripheral nervous system.

Anticholinergics are typically reversible competitive inhibitors of one of the two types of acetylcholine receptors, and are classified according to the receptors that are affected: *antimuscarinic* agents operate on the muscarinic acetylcholine receptors, and *antinicotinic* agents operate on the nicotinic acetylcholine receptors. The majority of anticholinergics are antimuscarinics.

Effects

When a significant amount of anticholinergic is taken into the body, a toxidrome known as *acute anticholinergic syndrome* may result. This may happen accidentally or intentionally as a form of recreational drug use. This class of drug is usually considered the least "fun" by experienced drug users, possibly due to the lack of euphoria caused by anticholinergics. Because most users do not enjoy the experience, they don't use it again, or very rarely. Risk of addiction is low in the anticholinergic class. Effects are usually more pronounced in the elderly, due to the decrease of acetylcholine production associated with age.

Possible effects of anticholinergics include:

- Ataxia; loss of coordination

Decreased mucus production in the nose and throat; consequent dry, sore throat
Xerostomia or dry mouth
Cessation of perspiration; consequent increased thermal dissipation through the skin leading to hot, red skin
Increased body temperature
Pupil dilation (mydriasis); consequent sensitivity to bright light (photophobia)
Loss of accommodation (loss of focusing ability, blurred vision — cycloplegia)
Double vision (diplopia)
Increased heart rate (tachycardia)
Urinary retention
Diminished bowel movement, sometimes ileus
Increased intraocular pressure, dangerous for people with narrow-angle glaucoma

Possible effects in the central nervous system resemble those associated with delirium, and may include:

- Confusion
- Disorientation
- Agitation
- Respiratory depression
- Short-term memory loss

- Inability to concentrate
- Wandering thoughts; inability to sustain a train of thought
- Incoherent speech
- Wakeful myoclonic jerking
- Unusual sensitivity to sudden sounds
- Illogical thinking
- Photophobia
- Visual disturbances
  - Periodic flashes of light
  - Periodic changes in visual field
  - Visual snow
  - Restricted or "tunnel vision"
- Visual, auditory, or other sensory hallucinations
  - Warping or waving of surfaces and edges
  - Textured surfaces
  - "Dancing" lines; "spiders", insects
  - Lifelike objects indistinguishable from reality
- Rarely: seizures, coma and death

Acute anticholinergic syndrome is completely reversible and subsides once all of the toxin has been excreted. Ordinarily, no specific treatment is indicated. However, in extreme cases, especially those that involves severe distortions of mental state, a reversible cholinergic agent such as physostigmine may be used.

Plant sources

The most common plants containing anticholinergic alkaloids are:

- Atropa belladonna (Deadly Nightshade)
Mandragora officinarum (Mandrake)
Hyoscamus niger (Henbane)
Datura species (Datura)

Pharmaceuticals

- Unclassified
  - benztropine (Cogentin®)
- Muscarinic receptor antagonists
  - Belladonna alkaloids
    - Scopolamine (L-Hyoscine)
    - Atropine (D/L-Hyoscyamine)
  - Synthetic and Semisynthetic
    - Dicyclomine

Flavoxate
Ipratropium
Oxybutynin

Pirenzepine
Tiotropium
Tolterodine (Detrusitol®)
Tropicamide
Solifenacin (Vesicare®)
Darifenacin (Enablex®)

- Nicotinic receptor antagonists
  - Ganglionic blocking agents
    - Trimethaphan
  - Nondepolarizing neuromuscular blocking agents
    - Atracurium

Doxacurium
Mivacurium
Pancuronium
Tubocurarine
Vecuronium

  - Depolarizing neuromuscular blocking agents

- Suxamethonium chloride

Many other drugs have anticholinergic properties, including cyclic antidepressants and the common allergy medications diphenhydramine (Benadryl) and its 8-chlorotheophylline salt dimenhydrinate (Dramamine), which are used medically for antihistaminergic and antiemetic purposes, and sometimes recreationally for their psychoactive effects. The common side effects of some SSRI antidepressants, such as Prozac (fluoxetine), often sweaty palms, are due to anticholinergic properties.

Some drugs, such as hydrocodone, are mixed with small amounts of an anticholinergic, such as Homatropine Methylbromide to discourage abuse.

Deliriants

The *deliriants* (or anticholinergics) are a special class of dissociatives which are antagonists for the acetylcholine receptors (unlike muscarine and nicotine which are agonists of these receptors). Deliriants are distinct from classical hallucinogens in that users will have conversations with people who aren't there, or become angry with a 'person' mimicking their actions, not realizing it is their own reflection in a mirror (a situation which could be dangerous if they became aggressive towards a glass mirror). The anticholinergics have effects akin to sleepwalking (particularly in that the subject has poor recall of the experience).

Included in this group are such Solanaceae plants as deadly nightshade, mandrake, henbane and datura (sometimes referred to as the Belladonna alkaloids), as well as a number of pharmaceutical drugs such as the antihistamine diphenhydramine (Benadryl) and the antiemetics dimenhydrinate (Dramamine or Gravol) and scopolamine.

In addition to the danger of being far more out of touch with reality than with other drugs, and retaining a truly fragmented dissociation from regular consciousness without being immobilized, the anticholinergics are toxic, can cause death due to overdose, and also include plenty of uncomfortable side effects including an intense drying effect where sweat, saliva, mucus and urination are prevented, as well as a pronounced dilation of the pupils which can last for several days resulting in sensitivity to light, blurry vision and inability to read.

Deliriants are common to European mythology, including the plants mandrake, deadly nightshade, and various datura species.

3-Quinuclidinyl benzilate

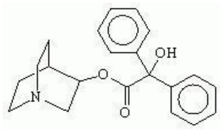

Diagram of a BZ molecule

3-quinuclidinyl benzilate (QNB), empirical formula C21H23NO3, full chemical name 1-azabicyclo[2.2.2]oct-3-yl ±-hydroxy-±-phenylbenzeneacetate, is an odorless military incapacitating agent. Its NATO code is *BZ*. The Iraqi incapacitating agent Agent 15 is believed either to be the same as or similar to BZ.

BZ is a glycolate anticholinergic compound related to atropine, scopolamine, hyoscyamine, and other deliriants. Dispersal would be as an aerosolized solid (primarily for inhalation) or as agent dissolved in one or more solvents for ingestion or percutaneous absorption.

Acting as a competitive inhibitor of acetylcholine at postsynaptic and postjunctional muscarinic receptor sites in smooth muscle, exocrine glands, autonomic ganglia, and the brain, BZ decreases the effective concentration of acetylcholine seen by receptors at these sites. Thus, BZ causes peripheral nervous system (PNS) effects that in general are the opposite of those seen in nerve agent poisoning. Central nervous system (CNS) effects include stupor, confusion, and confabulation with concrete and panoramic illusions and hallucinations, and with regression to automatic "phantom" behaviors such as plucking and disrobing.

Physostigmine, which increases the concentration of acetylcholine in synapses and in neuromuscular and neuroglandular junctions, is a specific antidote.

Production of BZ is controlled under schedule 2 of the Chemical Weapons Convention.

Development and military use

Following World War II, the United States military investigated a wide range of possible nonlethal, psychobehavioral chemical incapacitating agents to include psychedelic indoles such as lysergic acid diethylamide (LSD-25) and marijuana derivatives, certain tranquilizers like ketamine or fentanyl, as well as several glycolate anticholinergics. One of the anticholinergic compounds, 3-quinuclidinyl benzilate, was assigned the NATO code BZ and was weaponized at the beginning of the 1960s for possible battlefield use. This agent was reportedly employed by American troops as a counterinsurgency weapon in Vietnam, but supposedly otherwise never saw operational use. It has been rumored that BZ was administered to American troops in order to increase their fighting power and improve their performance, but this rumor is very disputed. This rumor is a major reference point in the film Jacob's Ladder (1990), although the film does not discuss BZ specifically. Destruction of American stockpiles began in 1988 and is now complete.

In February 1998, the British Ministry of Defense released an intelligence report that accused Iraq of having stockpiled large amounts of a glycolate anticholinergic incapacitating agent known as Agent 15. Agent 15 is an alleged Iraqi incapacitating agent that is likely to be chemically either identical to BZ or closely related to it. Agent 15 was reportedly stockpiled in large quantities prior to and during the Persian Gulf War. The combination of anticholinergic PNS and CNS effects aids in the diagnosis of patients exposed to these agents.

Also in 1998, there were allegations that elements of the Yugoslav People's Army used incapacitating agents against fleeing Bosnian refugees in 1995 that caused hallucinations and irrational behavior. [1] Physical evidence of BZ use in Bosnia remains elusive, however.

Sources other than military

BZ and related anticholinergic compounds can be synthesized in clandestine laboratories, but its illicit use is nonexistant, because of its unpleasant effects. 3-quinuclidinyl benzilate, called QNB in the scientific community, is used in pharmacology as a muscarinic receptor antagonist.

Physiochemical characteristics

BZ is odorless. It is stable in most solvents, with a half-life of three to four weeks in moist air; even heat-producing munitions can disperse it. It is extremely persistent in soil and water and on most surfaces. It is also soluble in propylene glycol, DMSO, and other solvents.

Detection and protection

Because BZ is odorless and nonirritating, and because clinical effects are not seen until after a latent period of 30 minutes to 24 hours, exposure could occur without the knowledge of casualties. No currently available field military or civilian detector is designed to disclose the presence of BZ or other anticholinergic compounds in the environment. Confirmation of the exact chemical involved in an incapacitating agent exposure would have to await laboratory analysis of environmental specimens containing the agent. The HEPA filter in the canister of the chemical protective mask prevents exposure of the face and respiratory tract to aerosolized BZ. The chemical protective ensemble protects the skin against contact with BZ or other incapacitating agents dispersed as fine solid particles or in solution. Protection against ingestion would depend upon a high index of suspicion for BZ contaminated food or drink.

Toxicokinetics

BZ may be dispersed as an aerosolized collection of small particles. Alternately, it may be dissolved in a solvent such as DMSO to enhance percutaneous absorption. Bioavailability via ingestion and by inhalation of particles 1 micrometre in size approximates 80%, and 40 to 50%, respectively, of a parenterally delivered dose of BZ. Percutaneous absorption of BZ dissolved in propylene glycol yields, after a latent period of up to 24 hours, serum levels approximately 5 to 10% of those achieved with intravenous or intramuscular administration. Although inhalation of aerosolized BZ is probably the greatest risk on the battlefield, terrorists may choose to disseminate BZ in forms that provide significant opportunities for ingestion and absorption through the skin.

Following absorption, BZ is systemically distributed to most organs and biological tissues of the body. Its ability to reach synapses and neuromuscular and neuroglandular junctions throughout the body is responsible for its PNS effects, whereas its ability to cross the blood-brain barrier confers upon it the ability to cause CNS effects. Atropine and hyoscyamine both cross the placenta and can be found in small quantities in breast milk; whether this is also true for BZ is unclear.

Metabolism of BZ would be expected to occur primarily in the liver, with elimination of unchanged agent and metabolites chiefly in the urine.

Toxicity

The characteristic that makes BZ an incapacitating rather than a toxic chemical warfare agent is its high safety ratio. The amount required to produce effects is a thousand or more fold less than a fatal dose of the compound. In terms of Ct products (admittedly a sometimes problematic way of measuring dosage received after aerosol exposure), the ICt50 (the Ct product needed to produce incapacitation in 50% of an exposed group) for BZ is 112 mg·min/m^3, whereas the Ld50 is estimated to be 200,000 mg·min/m^3.

Toxicodynamics (mechanism of action)

The agent BZ and other anticholinergic glycolates act as competitive inhibitors of the neurotransmitter acetylcholine neurons (1) at postjunctional muscarinic receptors in cardiac and smooth muscle and in exocrine (ducted) glands and (2) at postsynaptic receptors in neurons. As the concentration of BZ at these sites increases, the proportion of receptors available for binding to acetylcholine decreases and the end organ "sees" less acetylcholine. (One way of visualizing this process is to imagine BZ coating the surface of the end organ and preventing acetylcholine from reaching its receptors.) Because BZ has little to no agonist activity with respect to acetylcholine, high concentrations of BZ essentially substitute a "dud" for acetylcholine at these sites and lead to clinical effects reflective of understimulation of end organs.

Clinical effects

Peripheral Effects:

- Mydriasis, blurred vision

Dry mouth, skin

Initially rapid heart rate declining to normal or slow heart rate over time

Possible flushing of the skin

The PNS effects of BZ are, in general, readily understood as those of understimulation of end organs and are qualitatively similar to those of atropine. Decreased stimulation of eccrine and apocrine sweat glands in the skin results in dry skin (an affected patient can be "dry as a bone") and a reduction in the ability to dissipate heat by evaporative cooling. The skin becomes warm ("hot as a hare") partly from decreased sweating and partly from compensatory cutaneous vasodilatation (the patient becomes "red as a beet," with a so-called atropine flush) as the body attempts to shunt a higher proportion of core-temperature blood as close as possible to the surface of the skin. With decreased heat loss, the core temperature itself rises.

Understimulation of other exocrine glands leads to xerostomia (dry mouth, another way in which the patient is "dry as a bone"), thirst, and decreased secretions from lacrimal, nasal, bronchial, and gastrointestinal glands.

Decreased cholinergic stimulation of pupillary sphincter muscles allows alpha-adrenergically innervated pupillary dilating muscles to act essentially unopposed, resulting in mydriasis. (In fact, the cosmetic effect of mydriasis in women who applied extracts of deadly nightshade topically to their eyes explains the name "belladonna" given to this plant.) Similar effects on cholinergic ciliary muscles produce paralysis of accommodation. Classically, the patient is described as being "blind as a bat". Other smooth muscle effects from BZ intoxication include decreased bladder tone and decreased urinary force with possibly severe bladder distention (yet another way in which the patient may be said to be "dry as a bone").

BZ typically raises the heart rate initially, but hours later, depending on the dose of BZ, the heart rate falls to normal or may become slow. Either the peripheral vagal blockade has ceased or the stimulation of the vagal nucleus has occurred.

Neither atropine nor BZ can act directly at the postjunctional nicotinic receptors found in skeletal muscle, but BZ-exposed patients nonetheless exhibit muscle weakness. This weakness, along with incoordination, heightened stretch reflexes, and ataxia, is probably due to the effects of BZ at CNS sites.

The PNS effects of BZ are essentially side effects that are useful in diagnosis, but incidental to the CNS effects for which the incapacitating agents were developed. These CNS effects include a dose-dependent decrease in the level of consciousness, beginning with drowsiness and progressing through sedation to stupor and coma. The patient is often disoriented to time and place. Disturbances in judgment and insight appear. The patient may abandon socially imposed restraints and resort to vulgar and inappropriate behavior. Perceptual clues may no longer be readily interpretable, and the patient is easily distracted and may have memory loss, most notably short-term memory. In the face of these deficits, the patient still tries to make sense of his environment and will not hesitate to make up answers on the spot to questions that confuse him. Speech becomes slurred and often senseless, and loss of inflection produces a flat, monotonous voice. References become concrete and semiautomatic with colloquialisms, clichés, profanity, and perseveration. Handwriting also deteriorates. Semiautomatic behavior may also include disrobing (perhaps partly because of increased body temperature), mumbling, and phantom behaviors such as constant picking, plucking, or grasping motions ("woolgathering" or carphology).

It should be noted that BZ was supposedly administered to soldiers during the Vietnam War in the film Jacob's Ladder, but the specified effects are not accurate and possibly exaggerated. It has not been proven that BZ sends people exposed to it in a homicidal frenzy, as the film suggests.

Central effects

- Disturbances in level of consciousness

Misperceptions and difficulty in interpretation (delusions, hallucinations)
Poor judgment and insight (denial of illness)
Short attention span, distractibility, impaired memory (particularly recent)
Slurred speech, perseveration
Disorientation

Ataxia
Variability (quiet/restless)

Central nervous system mediated perceptual disturbances in BZ poisoning include both illusions (misidentification of real objects) and hallucinations (the perception of objects or attributes that have no objective reality). (Although the phrase "mad as a hatter" refers to poisoning from mercury formerly used by hatters on felt, it can just as well serve as a reminder of CNS effects from anticholinergics.) Hallucinations resulting from anticholinergics such as BZ tend to be realistic, distinct, easily identifiable (often commonly encountered objects or persons), panoramic, and difficult to distinguish from reality. They also have the tendency to decrease in size during the course of the intoxication. This is in contrast to the typically vague, ineffable, and transcendent-appearing hallucinations induced by psychedelics such as LSD.

Another prominent CNS finding in BZ poisoning is behavioral lability, with patients swinging back and forth between quiet confusion and self-absorption in hallucinations, to frank combativeness. Moreover, as other symptoms begin to resolve, intermittent paranoia may be seen. Automatic behaviors common during resolution include the crawling or climbing motions called "progresso obstinato" in old descriptions of dementia.

BZ produces effects not just in individuals, but also in groups. Sharing of illusions and hallucinations (folie à deux, folie en famille, and "mass hysteria") is exemplified by two BZ-intoxicated individuals who would take turns smoking an imaginary cigarette clearly visible to both of them but to no one else. [Clarification] When one observed subject mumbled, "Gotta cigarette?" His delirious companion held out an invisible pack, he followed with, "S'okay, don't wanna take your last one." In another test it was reported two victims of BZ played tennis with imaginary rackets.

Time course of effects

Clinical effects from ingestion or inhalation of BZ appear after an asymptomatic or latent period that may be as little as 30 minutes, or as long as 20 hours; the usual range is 0.5 to 4 hours, with a mean of 2 hours. However, effects may not appear up to 36 hours after skin exposure to BZ.

Once effects appear, their duration is typically 72 to 96 hours and are dose-dependent. Following an ICt50 of BZ, severe effects may last 36 hours, but mild effects may persist for an additional day.

The clinical course from BZ poisoning can be divided into the following four stages:

1. Onset or induction (zero to four hours after exposure), characterized by parasympathetic blockade and mild CNS effects.
2. Second phase (4 to 20 hours after exposure), characterized by stupor with ataxia and hyperthermia.
3. Third phase (20 to 96 hours after exposure), in which full-blown delirium is seen but often fluctuates from moment to moment.
4. Fourth phase, or resolution, characterized by paranoia, deep sleep, reawakening, crawling or climbing automatisms, and eventual reorientation.

Differential diagnosis

The differential diagnosis for irrational and confused patients is a long one and includes anxiety reactions as well as intoxication with a variety of agents, to include hallucinogenic indoles (such as LSD), cannabinoids (such as the delta-9-tetrahydrocannabinol in marijuana), lead, barbiturates, and bromides. All of these conditions can lead to restlessness, lightheadedness (with associated vertigo and ataxia), confusion, and erratic behavior with or without vomiting. Clues that specifically point to BZ or a related compound are the combination of anticholinergic PNS effects ("dry as a bone," "hot as a hare," "red as a beet," and "blind as a bat") with the CNS effects ("mad as a hatter") of slurred and monotonous speech, automatic behavior (perseveration, disrobing, and phantom behaviors (such as "woolgathering"), and vivid, realistic, describable hallucinations (decreasing in size over time) in a patient slipping into and out of delirium.

Signs and symptoms

- Restlessness
- Dizziness or giddiness
- Failure to obey orders
- Confusion
- Erratic behavior
- Stumbling or staggering
- Drymouth (cottonmouth)
- Tachycardia at rest
- Elevated temperature
- Flushing of face
- Blurred vision
- Pupillary dilation
- Slurred or nonsensical speech

- Hallucinations

- Disrobing
- Mumbling
- Stupor and coma.
- Inappropriate smiling or laughter
- Irrational fear
- Distractability
- Difficulty expressing self
- Elevated blood pressure
- Stomach cramps and vomiting
- Euphoric, relaxed, unconcerned attitude
- Hypotension and/or dizziness on sudden standing
- Tremor

- Clinging or pleading
- Seemingly reasonless crying
- Decrease in disturbance with reassurance

Anticholinergics

- Indoles (Schizophrenic psychosis may mimic in some respects.)

Cannabinols

Anxiety reaction

Atropine intoxication from MARK I autoinjector use in a patient not exposed to nerve agents may create similar PNS effects to those seen in BZ intoxication. However, marked confusion from atropine is not normally seen until a total of six or seven autoinjectors have been given (in a hot, dehydrated, or battle-stressed individual, less atropine would probably suffice). Circumstantial evidence may be helpful in this situation. Heat stroke may also generate hot, dry, and confused or stuporous casualties and needs to be considered in the differential diagnosis. Patients with anxiety reactions are usually oriented to time, place, and person but may be trembling, crying, or otherwise panicked. The classic picture of unconcern or "la belle indifférence" may characterize a patient with a conversion reaction, but these patients are also likely to be oriented and lack the anticholinergic PNS signs of BZ poisoning.

Medical management

The admonition to protect oneself first may be difficult when dealing with any intoxication involving a latent period, since initially asymptomatic exposure to health care providers may already have occurred during the same time frame in which patients were exposed. Protection of medical staff from already absorbed and systemically distributed BZ in a patient is not needed.

General supportive management of the patient includes decontamination of skin and clothing (ineffective for already absorbed agent but useful in preventing further absorption of any agent still in contact with the patient), confiscation of weapons and related items from the patient, and observation. Physical restraint may be required in moderately to severely affected patients. The greatest risks to the patient's life are (1) injuries from his or her own erratic behavior (or from the behavior of similarly intoxicated patients) and (2) hyperthermia, especially in patients who are in hot or humid environments or are dehydrated from overexertion or insufficient water intake. A severely exposed patient might be comatose with serious cardiac arrhythmias and electrolyte disturbances. Management of heat stress assumes a high priority in these patients. Because of the prolonged time course in BZ poisoning, consideration should always be given to evacuation to a higher echelon of care.

As a competitive inhibitor of acetylcholine, BZ effectively decreases the amount of acetylcholine "seen" by postsynaptic and postjunctional receptors throughout the body. Specific antidotal therapy in BZ poisoning is therefore geared toward raising the concentration of acetylcholine in these synapses and junctions. Any compound that causes a rise in acetylcholine concentration can potentially overcome BZ-induced inhibition and

restore normal functioning; even the nerve agent VX has been shown to be effective when given under carefully controlled conditions. The specific antidote of choice in BZ poisoning is the carbamate anticholinesterase physostigmine (eserine; Antilirium®), which temporarily raises acetylcholine concentrations by binding reversibly to anticholinesterase on the postsynaptic or postjunctional membrane. Physostigmine is similar in many ways to pyridostigmine and is equally effective when used as a pre-exposure antidotal enhancer ("pretreatment") in individuals at high risk for subsequently encountering soman. However, physostigmine is not used for this purpose because the doses required cause vomiting through CNS mechanisms. In the case of BZ poisoning, a nonpolar compound such as physostigmine is used specifically because penetration into the brain is required in those individuals who already have CNS effects from BZ.

In BZ-intoxicated patients, physostigmine is minimally effective during the first four hours after exposure but is very effective after four hours. Oral dosing generally requires one and a half times the amount of antidote as does IM or IV administration. However, effects from a single intramuscular injection of physostigmine last only about 60 minutes, necessitating frequent re-dosing. It must be emphasized that physostigmine does not shorten the clinical course of BZ poisoning and that relapses will occur if treatment is discontinued prematurely. The temptation to substitute a slow intravenous infusion for intramuscular injections should be tempered by the awareness that IV infusion may lead to nerve-agent-like bradycardia, and too rapid infusion might cause arrhythmias, excessive secretions (to the point of compromising air exchange), and convulsions. Moreover, the sodium bisulfite in commercially available preparations of physostigmine may cause life-threatening allergic responses.

Suggested dosages for physostigmine in the treatment of BZ poisoning follow:

Test dose: If the diagnosis is in doubt, a dose of 1 mg might be given. If a slight improvement occurs, routine dosing should be given.

Routine dosing: Doses of about 45 µg/kg for adults have been recommended. This might be modified by the response. A mental status examination should be done every hour and the dose and time interval of dosing should be modified according to whether the mental status is improved or not. As the patient improves, the dosage requirement will decrease.

Routes of administration:

- IM: 45 µg/kg in adults (20 µg/kg in children)
- IV: 30 µg/kg slowly (1 mg/min)
- PO: 60 µg/kg if patient is cooperative (because of bitter taste, consider diluting in juice)

For each route, titrate about every 60 minutes to mental status.

History and toxicity of physostigmine

The antagonism between physostigmine (the elixir of calabar bean) and atropine (tincture of belladonna) was first reported in 1864 by a physician who successfully treated prisoners who had become delirious after drinking tincture of belladonna. Physicians did not notice this report until the 1950s when atropine coma (in which 50 mg or so of atropine were given to certain psychiatric patients) was successfully treated with physostigmine after

the "therapeutic benefit" had been attained. Again, this went unnoticed until a controlled study, reported in 1967, indicated that anticholinergic intoxication could be successfully, albeit transiently, reversed by physostigmine.

A recent textbook of emergency medicine stated that physostigmine should be used only as "a last resort." It would seem that when a patient needs "last resort" care is the absolute wrong time to administer a potent cholinesterase inhibitor.

The administration of physostigmine by the IV route in a delirious but conscious and otherwise healthy patient is not without peril. It is sometimes difficult to keep a delirious patient quiet long enough to administer the drug (at 1 mg/min is the marketed solution of 1 mg/ml). Even if administered correctly (very slowly), the heart rate may decline from 110 to 45 beat/min over a period of 1 to 2 minutes. The difference in the onset of the effects after IM and IV administration of physostigmine is a matter of only several minutes. Since its use is rarely lifesaving, this slight difference in time of response is inconsequential.

Physostigmine is a safe and effective antidote if used properly. In a conscious and delirious patient it will produce very effective but transient reversal of both the peripheral and central effects of cholinergic blocking compounds. Its use by the IV route is not without hazards. It absolutely should NOT be used in a patient with cardiorespiratory compromise, hypoxia, or acid-base imbalance with a history of seizure disorders or arrhythmias.

Triage

An immediate casualty (possible but unlikely) would be one with cardiorespiratory compromise or severe hyperthermia. Immediate attention to ventilation, hemodynamic status, and temperature control could be lifesaving. Because of its dangers in a hypoxic or hemodynamically challenged patient, physostigmine should be considered a second-line management option to be used only if adequate attention can simultaneously be given to temperature and other vital signs.

The delayed casualty would present with pronounced or worsening anticholinergic signs. Physostigmine should definitely be considered in this kind of patient.

A minimal casualty from a strictly medical standpoint might have mild PNS or CNS anticholinergic effects. Given the time course of BZ intoxication, however, these patients should not be considered able to manage themselves or capable of routine return to duty and should be relieved of their weapons, observed, and, if the holding capacity at the current echelon is exceeded, evacuated.

An expectant casualty (also possible but unlikely) would have severe cardiorespiratory compromise in a situation in which treatment or evacuation resources are too limited to allow the necessary attention to be directed to him or her.

Return to duty

Given the time course of the intoxication, early return to duty is probably not a realistic possibility for the majority of casualties who may require observation and management for several days at the least.

Atropine

Systematic (IUPAC) name

(8-methyl-8-azabicyclo[3.2.1]oct-3-yl) 3-hydroxy-2-phenyl-propanoate

Identifiers

CAS number 51-55-8

ATC code A03**BA01** S01**FA01**

PubChem 174174

DrugBank APRD00807

Chemical data

Formula $C_{17}H_{23}NO_3$

Mol. weight 289.369

Pharmacokinetic data

Bioavailability **25%**

Metabolism 50% hydrolysed to tropine and tropic acid

Half life 2 hours

Excretion 50% excreted unchanged in urine

Therapeutic considerations

Routes oral, i.v., rectal

Atropine is a tropane alkaloid extracted from the deadly nightshade (Atropa belladonna) and other plants of the family Solanaceae. It is a secondary metabolite of these plants and serves as a drug with a wide variety of effects. Being potentially deadly, it derives its name from Atropos, one of the three Fates who, according to Greek mythology, chose how a person was to die.

Physiological effects and uses

Generally, atropine lowers the "rest and digest" activity of all muscles and glands regulated by the parasympathetic nervous system. This occurs because atropine is a competitive antagonist of the muscarinic acetylcholine receptors. (Acetylcholine is the main

neurotransmitter used by the parasympathetic nervous system.) Therefore, it may cause swallowing difficulties and reduced secretions.

Ophthalmic use

Topical atropine is used as a cycloplegic, to temporarily paralyze the accommodation reflex, and as a mydriatic, to dilate the pupils. Atropine degrades slowly, typically wearing off in 2 to 3 days, so tropicamide and phenylephrine is generally preferred as a mydriatic. In atropine-induced mydriasis, the mechanism of action involves blocking the contraction of the circular pupillary sphincter muscle which is normally stimulated by acetylcholine release, thereby allowing the radial pupillary dilator muscle to contract and dilate the pupil. Atropine is contraindicated in patients predisposed to narrow angle glaucoma.

Resuscitation

Injections of atropine are used in the treatment of bradycardia (an extremely low heart rate), asystole and pulseless electrical activity (PEA) in cardiac arrest. This works because the main action of the vagus nerve of the parasympathetic system on the heart is to slow it down. Atropine blocks that action and therefore may speed up the heart rate.

Atropine is also useful in treating first degree heart block, second degree heart block Type 1 Wenckebach, and also third degree heart block with a high Purkinje or AV-nodal escape rhythm. It is contraindicated in second degree heart block Type II Mobitz, and in third degree heart block with a low Purkinje or ventricular escape rhythm.

The main action of the parasympathetic nervous system is to stimulate the M2 muscarinic receptor in the heart, but atropine inhibits this action.

Secretions and bronchoconstriction

Atropine's actions on the parasympathetic nervous system inhibits salivary, sweat, and mucus glands. This can be useful in treating Hyperhidrosis and can prevent the death rattle of dying patients. Even though it has not been officially indicated for either of these purposes by the FDA, it has been used by physicians for these purposes.

Antidote for organophosphate poisoning

By blocking the action of acetylcholine at muscarinic receptors, atropine also serves as an antidote for poisoning by organophosphate insecticides and nerve gases. Troops who are likely to be attacked with chemical weapons often carry autoinjectors with atropine and obidoxime which can be quickly injected into the thigh. It is often used in conjunction with Pralidoxime chloride.

Some of the nerve gases attack and destroy acetylcholinesterase, so the action of acetylcholine becomes prolonged. Therefore, atropine can be used to reduce the effect of acetylcholine.

Side effects and overdoses

Adverse reactions to atropine include ventricular fibrillation, supraventricular or ventricular tachycardia, giddiness, nausea, blurred vision, loss of balance, dilated pupils, photophobia, and possibly, notably in the elderly, confusion, hallucinations, and excitation. These latter effects are due to the fact that atropine is able to cross the blood-brain barrier. Because of the hallucinogenic properties, some have used the drug recreationally, though this is very dangerous and often unpleasant.

In overdoses, atropine is poisonous. Atropine is sometimes added to other potentially addictive drugs; abuse of those drugs is then prevented by the unpleasant effects of atropine overdose.

Atropine can cause heart rate slowing when given at very low doses, presumably as a result of a weak partial agonist effect at the cardiac muscarinic receptors.

The antidote to atropine is physostigmine or pilocarpine.

Chemistry and pharmacology

Atropine is a racemic mixture of D-hyoscyamine and L-hyoscyamine, with most of its physiological effects due to L-hyoscyamine. Its pharmacological effects are due to binding to muscarinic acetylcholine receptors.

The most common atropine compound used in medicine is atropine sulfate (C17H23NO3)2. H2SO4. H2O, the full chemical name is 1± H, 5± H-Tropan-3-± ol (±)-tropate(ester), sulfate monohydrate.

History

Atropine extracts from the Egyptian henbane were used by Cleopatra in the last century B.C. to dilate her pupils, in the hope that she would appear more alluring.

In the Renaissance, women used the juice of the berries of Atropa belladonna to enlarge the pupils of their eyes, for cosmetic reasons; "bella donna" is Italian for "beautiful lady".

Atropine and its mydriatic effects were discovered in 1833 by the German chemist Friedrich Ferdinand Runge (1795-1867).

Natural sources

Atropine is found in many members of the Solanaceae family. The most commonly found sources are Atropa belladonna, Datura inoxia, D. metel, and D. stramonium. Other sources include members of the Brugmansia and Hyoscyamus genera. The Nicotiana genus (including the tobacco plant, N. tabacum) is also found in the Solanaceae family, but these plants do not contain atropine or other tropane alkaloids.

Legal status $_{\text{-only(US)}}$

Routes transdermal, ocular, (formerly oral, subcutaneous)

Scopolamine, also known as *hyoscine*, is a tropane alkaloid drug obtained from plants of the family Solanaceae (nightshades), such as henbane or jimson weed (Datura species). It is part of the secondary metabolites of plants.

It acts as a competitive antagonist at muscarinic acetylcholine receptors; it is thus classified as an anticholinergic.

In medicine, it is usually used in the form scopolamine hydrobromide. It can be used as a depressant of the central nervous system, though it can cause delirium in the presence of pain, mydriasis (pupillary dilation), and cycloplegia (paralysis of the eye muscles). When combined with morphine, it produces a tranquilized state known as twilight sleep and amnesia. Although originally used in obstetrics, it is now considered dangerous for that purpose. Sometimes side effects of scopolamine can be mistaken for symptoms of cancer

because of the nausea and anisocoria associated with brain tumors. However, scopolamine induced anisocoria clears up usually within 3 days.

It is used in ophthalmology to deliberately cause cycloplegia and mydriasis so that certain diagnostic procedures may be performed. It is also used in the treatment of iridocyclitis.

In otolaryngology it has been used to ease the trauma of intubation.

It is also an antiemetic (prevents vomiting), antivertigo (prevents dizziness), and antispasmodic (reduces smooth muscle contractions; although a derivate called butylscopolamine, that does not cross the blood-brain barrier, is used preferably). It can be used as a pre-anesthetic sedation, as an antiarrhythmic (preventing irregular heartbeat) during anesthesia, and for the prevention of motion sickness. Transdermal patches, (Scopoderm TTS patches), are available for the prevention of symptoms of travel sickness.

The drug is highly toxic and has to be used in minute doses. An overdose can cause delirium, delusions, paralysis, stupor and death.

The use of scopolamine as a truth drug was investigated by various intelligence agencies, including the CIA, during the 1950s. see: Project MKULTRA. It was found that, due to the hallucinogenic side effects of the drug, the truth was prone to distortion, and the project was subsequently abandoned.. Nazi doctor Josef Mengele experimented on scopolamine as an interrogation drug.

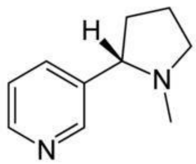
Scopolamine is used criminally as a date rape drug and as an aid to robbery, the most common act being the clandestine drugging of a victim's drink. It is preferred because it induces retrograde amnesia, or an inability to recall events prior to its administration. Victims of this crime are often admitted to a hospital in police custody, under the assumption that the patient is experiencing a psychotic episode. A telltale sign is a fever accompanied by a lack of sweat.

In Colombia a plant admixture containing scopolamine called Burundanga has been used shamanically for decades. In recent years its criminal use (as outlined above) has become an epidemic. Approximately fifty percent of emergency room admissions for poisoning in Bogotá have been attributed to scopolamine. Also in Caracas, Venezuela, crime related to burundanga techniques has multiplied in the last years.

Due to its effectiveness against sea-sickness it has become commonly used by scuba divers. However, this has led to the discovery of another side effect. In deep water, below 50–60 feet, some divers have reported pain in the eyes, but the pain subsides quickly if the diver ascends to a depth of 40 feet or less. Mydriatics can precipitate an attack of glaucoma in susceptible patients, so the medication should be used with extra caution among divers who intend to go below 50 feet.

In popular culture, scopolamine has achieved a moderate level of notoriety via its mention in the film I Was a Teenage Werewolf, where Dr. Alfred Brandon uses it as part of his endeavor to regress the titular character to his "primitive roots." According to one internet reviewer (http://twtd.bluemountains.net.au/Rick/liz_tw.htm), "Prepare the scopolamine" is the only scientifically accurate line in the entire film.

Nicotinic antagonists



Nicotine

Nicotinic acetylcholine receptors, or *nAChRs*, are ionotropic receptors that form ion channels in cells' plasma membranes. Like the other type of acetylcholine receptors, muscarinic acetylcholine receptors, their opening is triggered by the neurotransmitter acetylcholine, but they are also opened by nicotine (Siegel et al., 1999; Itier and Bertrand, 2001). Their action is inhibited by curare.

Nicotinic acetylcholine receptors are present in many tissues in the body. The neuronal receptors are found in the central nervous system and the peripheral nervous system. The neuromuscular receptors are found in the neuromuscular junctions of somatic muscles; stimulation of these receptors causes muscular contraction.

Structure

Nicotinic receptors, with a molecular weight of about 280 kDa, are made up of five receptor subunits, arranged symmetrically around the central pore. They share similarities with GABAA receptors, glycine receptors, and the type 3 serotonin receptors, which are all therefore classed into the nicotinicoid receptor family, or the signature Cys-loop proteins (Cascio, 2004).

Twelve types of nicotinic receptor subunits, ±2 through 10 and ^{2}2 through 4 (Itier and Bertrand, 2001), combine to form pentamers. The subunits are somewhat similar to one another, especially in the hydrophobic regions (Siegel et al., 1999). The muscle form of the nAChR consist of two ± subunits, a ^{2}, a ´ and either a ^{3} or an µ (Siegel et al., 1999; Itier and Bertrand, 2001; Giniatullin et al., 2005). The neuronal forms are much more heterogeneous, with a wide range of possible subunit combinations.

The sites for binding ACh are on the outside of the ± subunits near their N termini (Siegel et al., 1999). When the agonist binds, the ± subunits become more similar to the other subunits, the channel becomes more symmetrical (Colquhoun and Sivilotti, 2004), and a pore with a diameter of about 0.65 nm opens (Siegel et al., 1999).

Opening the channel

Nicotinic AChRs may exist in different interconvertible conformational states. Binding of nicotine stabilizes the open and desensitised states. Opening of the channel allows positively charged ions, in particular, sodium and calcium, to enter the cell.

The nAChR is permeable to Na± and K±, with some subunit combinations that are also permeable to Ca2+ (Siegel et al., 1999). The amount of sodium and potassium the channels allow through their pores (their conductance) is about 25 pS (Siegel et al., 1999), but the conductance depends on the actual subunit composition. Interestingly, because some

neuronal nAChRs are permeable to Ca2+, they can affect the release of other neurotransmitters (Itier and Bertrand, 2001). The channel usually opens rapidly and tends to remain open until the agonist diffuses away, usually for about 1 millisecond (Siegel et al., 1999). However, AChRs can open sometimes with only one agonist bound and in rare cases with no agonist bound, and they can close spontaneously even when ACh is bound, so ACh binding only creates a probability of pore opening, which increases as more ACh binds (Colquhoun and Sivilotti, 2004).

Effects

This activation of receptors by nicotine modifies the state of neurons through two main mechanisms. On one hand, the movements of cations cause a depolarization of the plasma membrane, which results in an excitation, particularly of neurons, but also by the activation of other voltage-gated ion channels. On the other hand, the entry of calcium acts, either directly or indirectly, on different intracellular cascades leading, for example, to the regulation of the activity of some genes or the release of neurotransmitters.

Roles

The subunits of the nicotinic receptors belong to a multigene family (16 members in human) and the assembly of combinations of subunits results in a large number of different receptors (For more information see the Ligand Gated Ion Channel database). These receptors, with highly variable kinetic, electrophysiological and pharmacological properties, respond differently to nicotine, at very different effective concentrations. This functional diversity allows them to take part in two major types of neurotransmission. Classical synaptic transmission (wiring transmission) involves the release of high concentrations of neurotransmitter, acting on immediately neighbouring receptors. In contrast, paracrine transmission (volume transmission) involves neurotransmitters released by synaptic buttons or varicosities, which then diffuse through the extra-cellular medium until they reach their receptors, which may be distant. Nicotinic receptors can also be found in different synaptic locations, for example the muscle nicotinic receptor always functions post-synaptically. The neuronal forms of the receptor can be found both post-synaptically (involved in classical neurotransmission) and pre-synaptically (where they can influence the release of other neurotranmsitters).

Subunits

To date 17 nAChR subunits have been identified, these are divided into muscle-type and neuronal-type subunits. Of these 17 subunits, ±2-±7 and ^{2}2-^{2}4 have been cloned in humans, the remaining genes identified in chick and rat genomes (Graham et al. 2002). The nAChR subunits have been divided into 4 subfamilies (I-IV) based on similarities in protein sequence. In addition, subfamily III has been further divided into 3 tribes.

Neuronal-type					Muscle-type
I	II	III			IV
		1	2	3	
α9, α10	α7, α8	α2, α3, α4, α6	β2, β4	β3, α5	α1, β1, δ, γ, ε

- *Alpha genes:* CHRNA1 *(muscle),* CHRNA2 *(neuronal),* CHRNA3, CHRNA4, CHRNA5, CHRNA6, CHRNA7, CHRNA8, CHRNA9, CHRNA10
  - Beta genes: CHRNB1 (muscle), CHRNB2 (neuronal), CHRNB3, CHRNB4,
  - Other genes: CHRND (delta), CHRNE (epsilon), CHRNG (gamma)

Tobacco

Nicotiana tabacum

Scientific classification

Kingdom: Plantae

Class: Magnoliopsida

Order: Solanales

Family: Solanaceae

Genus: **Nicotiana**

Species

Nicotiana acuminata
Nicotiana alata
Nicotiana attenuata
Nicotiana benthamiana
Nicotiana clevelandii
Nicotiana excelsior
Nicotiana forgetiana
Nicotiana glauca
Nicotiana glutinosa
Nicotiana langsdorffii
Nicotiana longiflora
Nicotiana obtusifolia
Nicotiana paniculata
Nicotiana plumbagifolia
Nicotiana quadrivalvis
Nicotiana repanda
Nicotiana rustica
Nicotianasuaveolens
Nicotiana sylvestris
Nicotiana tabacum
Nicotiana tomentosa

as of August 26, 2005

Tobacco (Nicotiana spp., L.)refers to a genus of broad-leafed plants of the nightshade family indigenous to North and South America, or to the dried and cured leaves of such plants. Tobacco leaves are often smoked (see tobacco smoking) in the form of a cigar or cigarette, or in a smoking pipe, or in a water pipe or a hookah. This can damage the lungs and can also potentially cause lung disorders such as asthma. Tobacco is also chewed, "dipped" (placed between the cheek and gum), and sniffed into the nose as finely powdered snuff.

Tobacco contains nicotine, a powerful neurotoxin that is particularly harmful to insects. All means of consuming tobacco result in the absorption of nicotine in varying amounts into the user's bloodstream, and over time the development of tolerance and dependence. Absorption quantity, frequency and speed seem to have a direct relationship with how strong a dependence and tolerance, if any, might be created. A lethal dose of nicotine is contained in as little as one half of a cigar or three cigarettes; however, only a small fraction of the nicotine contained in these products is actually released into the smoke, and most clinically significant cases of nicotine poisoning are the result of concentrated forms of the compound used as insecticides. Other active alkaloids in tobacco include harmala alkaloids.

Tobacco smoking carries significant risks including the potential to develop various cancers as well as strokes, and severe cardiovascular and respiratory diseases. [1] Significantly shorter life expectancies have been associated with tobacco smoking. [2] Many jurisdictions have enacted smoking bans in an effort to minimize possible damage to public health caused by tobacco smoking. The substantially increased risk of developing cancer as a result of tobacco usage seems to be due to the plethora of nitrosamines and other carcinogenic compounds found in tobacco and its residue as a result of anaerobic heating, either due to smoking or to flue-curing or fire-curing. The use of flue-cured or fire-cured smokeless tobacco in lieu of smoked tobacco reduces the risk of respiratory cancers but still carries significant risk of oral cancer. [3] In contrast, use of steam-cured chewing tobacco (snus), avoids the carcinogenicity by not generating nitrosamines, but the negative effects of the nicotine on the cardiovascular system and pancreas are not ameliorated.[4]

History

Native Americans used tobacco before Europeans arrived in North & South America, and early European settlers in North & South America learned to smoke and brought the practice back to Europe, where it became hugely popular. At extremely high doses, tobacco becomes hallucinogenic; accordingly, Native Americans generally did not use the drug recreationally. Rather, it was often consumed in extraordinarily high quantities and used as an entheogen; generally, this was done only by experienced shamans or medicine men. In addition to being smoked, uncured tobacco was often eaten, drunk as tobacco juice, or used in enemas. Early missionaries often reported on the state caused by tobacco, but as it spread into the west, it was no longer used in such large quantities or for entheogenic purposes. Religious use of tobacco is still common among many indigenous peoples, particularly those of South America.

With the arrival of Europeans, tobacco became one of the primary products fueling the colonization of the future American South, long before the creation of the United States. The

initial colonial expansion, fueled by the desire to increase tobacco production, was one cause of the first colonial conflicts with Native Americans and became a driving factor for the use of African slaves' labor.

In 1609, John Rolfe arrived at the Jamestown Settlement in Virginia. He is credited as the first man to successfully raise tobacco for commercial use at Jamestown. The tobacco raised in Virginia at that time, Nicotiana rustica, was not to the liking of the Europeans, but Rolfe had brought some seed for Nicotiana tabacum with him from Bermuda. Shortly after arriving, his first wife died, and he married Pocahontas, a daughter of Chief Powhatan. Although most of the settlers wouldn't touch the tobacco crop, Rolfe was able to make his fortune farming it for export at Varina Farms Plantation. When he left for England with Pocahontas, he was wealthy. When Rolfe returned to Jamestown following Pocahontas's death in England, he continued to improve the quality of tobacco. By 1620, 40,000 pounds of tobacco were shipped to England. By the time John Rolfe died in 1622, Jamestown was thriving as a producer of tobacco and Jamestown's population would top 4,000. Tobacco led to the importation of the colony's first black slaves as well as women from England in 1619.

The importation of tobacco into Europe was not without resistance and controversy, even in the 17th century. King James I of England (James VI of Scotland) wrote a famous polemic titled A Counterblaste to Tobacco in 1604 (published in 1672). In his essay, the king denounced tobacco use as "[a] custome lothsome to the eye, hatefull to the Nose, harmefull to the braine, dangerous to the Lungs, and in the blacke stinking fume thereof, neerest resembling the horrible Stigian smoke of the pit that is bottomelesse." In that same year, an English statute was enacted that placed a heavy protective tariff on every pound of tobacco brought into England.

Throughout the 17th and 18th centuries, tobacco continued to be the "cash crop" of the Virginia Colony, along with The Carolinas. Large tobacco warehouses filled the areas near the wharfs of new thriving towns such as Richmond and Manchester at the fall line (head of navigation) on the James River, and Petersburg on the Appomattox River.

Until 1883, tobacco excise tax accounted for one third of internal revenue collected by the United States government.

A historian of the American South in the late 1860s reported on typical usage in the region where it was grown: [1]

The chewing of tobacco was well-nigh universal. This habit had been widespread among the agricultural population of America both North and South before the war. Soldiers had found the quid a solace in the field and continued to revolve it in their mouths upon returning to their homes. Out of doors where his life was principally led the chewer spat upon his lands without offence to other men, and his homes and public buildings were supplied with spittoons. Brown and yellow parabolas were projected to right and left toward these receivers, but very often without the careful aim which made for cleanly living. Even the pews of fashionable churches were likely to contain these familiar conveniences. The large numbers of Southern men, and these were of the better class (officers in the Confederate army and planters, worth $20,000 or more, and barred from general amnesty) who presented themselves for the pardon of President Johnson, while they sat awaiting his pleasure in the ante-room at the White House, covered its floor with pools and rivulets of their spittle. An observant traveller in the South in 1865 said that in his belief seven-tenths of all persons above the age of twelve years, both male and female, used tobacco in some

form. Women could be seen at the doors of their cabins in their bare feet, in their dirty one-piece cotton garments, their chairs tipped back, smoking pipes made of corn cobs into which were fitted reed stems or goose quills. Boys of eight or nine years of age and half-grown girls smoked. Women and girls "dipped" in their houses, on their porches, in the public parlors of hotels and in the streets.

As a lucrative crop, tobacco has been the subject of a great deal of biological and genetic research. The economic impact of Tobacco Mosaic disease was the impetus that led to the isolation of Tobacco mosaic virus, the first virus to be identified; the fortunate coincidence that it is one of the simplest virii and can self-assemble from purified nucleic acid and protein led in turn to the rapid advancement of the field of virology. The 1946 Nobel Prize in Chemistry was shared by Wendell Meredith Stanley for his 1935 work crystallizing the virus, and showing that it still remains active.

Etymology

The Spanish word "tabaco" is thought to have its origin in Arawakan language, particularly, in the Taino language of the Caribbean, said to refer to a roll of these leaves (according to Bartolome de Las Casas, 1552) or to the "tabago", a kind of y-shaped pipe for sniffing tobacco smoke (according to Oviedo, the leaves themselves were referred to as Cohiba, but Sp. tabaco (also It. tobacco) was commonly used to define medicinal herbs from 1410, originating from the Arabic "tabbaq", reportedly since the 9th century, as the name of various herbs. The word might then be European, and later applied to this plant from the Americas.

Sowing

Tobacco seeds are scattered onto the surface of the soil, as their germination is activated by light. In colonial Virginia, seedbeds were fertilized with wood ash or animal manure (frequently powdered horse manure). Seedbeds were then covered with branches to protect the young plants from frost damage. These plants were left to grow until around April.

In the nineteenth century, young plants came under increasing attack from the flea beetle (Epitrix cucumeris or Epitrix pubescens), causing destruction of half the United States tobacco crop in 1876. In the years afterward, many experiments were attempted and discussed to control the flea beetle. By 1880 it was discovered that replacing the branches with a frame covered by thin fabric would effectively protect plants from the beetle. This practice spread until it became ubiquitous in the 1890s.

Today, in the United States, unlike other countries, tobacco is often fertilized with the mineral apatite in order to partially starve the plant for nitrogen, which changes the taste. This (together with the use of licorice and other additives) accounts for the different flavor of American cigarettes from those available in other countries. There is, however, some suggestion that this may have adverse health effects attributable to the polonium content of apatite.

Transplanting

After the plants have reached a certain height, they are transplanted into fields. This was originally done by making a relatively large hole in the tilled earth with a tobacco peg, then placing the small plant in the hole. Various mechanical tobacco planters were invented throughout the late 19th and early 20th century to automate this process, making a hole, fertilizing it, and guiding a plant into the hole with one motion.

Harvest

Tobacco is harvested in one of two ways. In the oldest method, the entire plant is harvested at once by cutting off the stalk at the ground with a curved knife. In the nineteenth century, bright tobacco began to be harvested by pulling individual leaves off the stalk as they ripened. The leaves ripen from the ground upwards, so a field of tobacco may go through several "pullings" before the tobacco is entirely harvested, and the stalks may be turned into the soil. "Cropping" or "pulling" are terms for pulling leaves off tobacco. Leaves are cropped as they ripen, from the bottom of the stalk up. The first crop at the very bottom of the stalks are called "sand lugs", as they are often against the ground and are coated with dirt splashed up when it rains. Sand lugs weigh the most, and are most difficult to work with. Originally

workers cropped the tobacco and placed it on mule-pulled sleds. Eventually tractors with wagons were used to transport leaves to the stringer, an apparatus which uses twine to sew leaves onto a stick .

Some farmers use "tobacco harvesters" - basically a trailer pulled behind a tractor. The harvester is a wheeled sled or trailer that has seats for the croppers to sit on and seats just in front of these for the "stringers" to sit on. The croppers pull the leaves off in handfuls, and pass these to the "stringer", who loops twine around the handfuls of tobacco and hangs them on a long wooden square pole. Traditionally, the croppers, down in the dark and wet, with their faces getting slapped by the huge tobacco leaves, were men, and the stringers seated on the higher elevated seats were women. The harvester has places for 4 teams of workers: 8 people cropping and stringing, plus a packer who takes the heavy strung poles of wet green tobacco from the stringers and packs them onto the pallet section of the harvester, plus a driver, making the total crew of each harvester 10 people. Interestingly, the outer seats are suspended from the harvester - slung out over to fit into the aisles of tobacco. As these seats are suspended it is important to balance the weight of the 2 outside teams (similar to a playground see-saw). Having too heavy or light a person in an unbalanced combination often results in the harvester tipping over especially when turning around at the end of a lane. Water tanks are a common feature on the harvester due to heat, and danger of dehydration for the workers. Salt tablets sometimes get used as well.

Pests

Pests of tobacco include the moths Endoclita excrescens, Manduca sexta (the Tobacco hornworm), and Manduca quinquemaculata. Other Lepidoptera whose larvae use tobacco as a food plant include Angle Shades, Cabbage Moth, Mouse Moth, Nutmeg Moth, Setaceous Hebrew Character and Turnip Moth. The dry tobacco leaves and cigarettes are sometimes used as food for the Cigarette Beetle (Lasioderma serricorne).

Curing

Cut plants or pulled leaves are immediately transferred to tobacco barns (kiln houses), where they will be cured. Curing methods varies with the type of tobacco grown, and tobacco barn design varies accordingly. Air-cured tobacco is hung in well-ventilated barns and allowed to dry over a period of weeks. Fire-cured tobacco is hung in large barns where smoldering fires of hardwoods are kept burning. Flue-cured tobacco was originally strung onto tobacco sticks, which were hung from tier-poles in curing barns (Aus: kilns, also traditionally called Oasts). These barns have flues which run from externally-fed fire boxes, heat-curing the tobacco without exposing it to smoke. Traditional curing barns in the U.S. are falling into disuse, as the trend toward more efficient prefabricated metal "bulk bars", allows greater efficiency. Curing and subsequent aging allows for the slow oxidation and degradation of carotenoids in tobacco leaf. This produces certain compounds in the tobacco leaves very similar and give a sweet hay, tea, rose oil, or fruity aromatic flavor that contribute to the "smoothness" of the smoke. Starch is converted to sugar which glycates protein and is oxidized into advanced glycation endproducts (AGEs), a caramelization process that also

adds flavor. Inhalation of these AGEs in tobacco smoke contributes to atherosclerosis and cancer[2].

Unaged or low quality tobacco is often flavoured with these naturally occurring compounds. Tobacco flavoring is a significant part of a multi-million dollar industry.

The aging process continues for a period of months and often extends into the post-curing process.

Post-cure processing

After tobacco is cured, it is moved from the curing barn into a storage area for processing. If whole plants were cut, the leaves are removed from the tobacco stalks in a process called stripping. For both cut and pulled tobacco, the leaves are then sorted into different grades. In colonial times, the tobacco was then "prized" into hogsheads for transportation. In bright tobacco regions, prizing was replaced by stacking wrapped "hands" into loose piles to be sold at auction. Today, most cured tobacco is baled before sales under contract.

Other Types

Aromatic Fire-cured

Aromatic Fire-cured smoking tobacco is a robust variety of tobacco used as a condimental for pipe blends. It is cured by smoking over gentle fires. In the United States, it is grown in the western part of Tennessee, Western Kentucky and in Virginia. Latakia is produced from oriental varieties of N. tabacum. The leaves are cured and smoked over smoldering fires of local hardwoods and aromatic shrubs in Cyprus and Syria. Latakia has a pronounced flavor and a very distinctive aroma, and is used in the so-called Balkan and English-style pipe tobacco blends.

Fire-cured tobacco grown in Kentucky and Tennessee is used in some chewing tobaccos, moist snuff, some cigarettes and as a condiment leaf in pipe tobacco blends. It has a rich, slightly floral taste, and adds body and aroma to the blend.

Brightleaf tobacco

Prior to the American Civil War, the tobacco grown in the US was almost entirely fire-cured dark-leaf. This was planted in fertile lowlands, used a robust variety of leaf, and was fire cured or air cured.

Sometime after the War of 1812, demand for a milder, lighter, more aromatic tobacco arose. Ohio and Maryland both innovated quite a bit with milder varieties of the tobacco plant. Farmers around the country experimented with different curing processes. But the breakthrough didn't come until 1854.

It had been noticed for centuries that sandy, highland soil produced thinner, weaker plants. Captain Abisha Slade, of Caswell County, North Carolina had a good deal of infertile, sandy soil, and planted the new "gold-leaf" varieties on it. Slade owned a slave, Stephen, who accidentally produced the first real bright tobacco. He used charcoal to restart a fire used to

cure the crop. The surge of heat turned the leaves yellow. Using that discovery, Slade developed a system for producing bright tobacco, cultivating on poorer soils and using charcoal for heat-curing.

News spread through the area pretty quickly. The worthless sandy soil of the Appalachian piedmont was suddenly profitable, and people rapidly developed flue-curing techniques, a more efficient way of smoke-free curing. By the outbreak of the War, the town of Danville, Virginia actually had developed a bright-leaf market for the surrounding area in Caswell County, North Carolina and Pittsylvania County, Virginia.

Danville was also the main railway head for Confederate soldiers going to the front. These brought bright tobacco with them from Danville to the lines, traded it with each other and Union soldiers, and developed quite a taste for it. At the end of the war, the soldiers went home and suddenly there was a national market for the local crop. Caswell and Pittsylvania counties were the only two counties in the South that experienced an increase in total wealth after the war.

White burley

In 1864, George Webb of Brown County, Ohio planted Red Burley seeds he had purchased, and found that a few of the seedlings had a whitish, sickly look. He transplanted them to the fields anyway, where they grew into mature plants but retained their light color. The cured leaves had an exceedingly fine texture and were exhibited as a curiosity at the market in Cincinnati. The following year he planted ten acres (40,000 m^2) from seeds from those plants, which brought a premium at auction. The air-cured leaf was found to be mild tasting and more absorbent than any other variety. White Burley, as it was later called, became the main component in chewing tobacco, American blend pipe tobacco, and American-style cigarettes. The white part of the name is seldom used today, since red burley, a dark air-cured variety of the mid-1800s, no longer exists.

Shade tobacco

It is not well known that the northern US state of Connecticut is also one of the important tobacco-growing regions of the country. Long before Europeans arrived in the area, Native Americans harvested wild tobacco plants that grew along the banks of the Connecticut River. Today, the Connecticut River valley north of Hartford, Connecticut is known as Tobacco Valley, and the fields and drying sheds are visible to travelers on the road to and from Bradley Field, the major Connecticut airport. The tobacco grown here is known as shade tobacco, and is used as outer wrappers for some of the world's finest cigars.

Early Connecticut colonists acquired from the Native Americans the habit of smoking tobacco in pipes and began cultivating the plant commercially, even though the Puritans referred to it as the "evil weed". The plant was outlawed in Connecticut in 1650, but in the 1800s as cigar smoking began to be popular, tobacco farming became a major industry, employing farmers, laborers, local youths, southern African Americans, and migrant workers.

Working conditions varied from pleasant summer work for students, to backbreaking exploitation of migrants. Each tobacco plant yields only 18 leaves useful as cigar wrappers, and each leaf requires a great deal of individual manual attention after harvesting, some of which must be carried out in the drying sheds, where the temperature exceeds 100 degrees Fahrenheit.

In 1921, Connecticut tobacco production peaked, at 31,000 acres (125 km^2) under cultivation. The rise of cigarette smoking and the decline of cigar smoking has caused a corresponding decline in the demand for shade tobacco, reaching a minimum in 1992 of 2,000 acres (8 km^2) under cultivation. Since then, however, cigar smoking has become more popular again, and in 1997 tobacco farming had risen to 4,000 acres (16 km^2). The industry has weathered some major catastrophes, including a devastating hailstorm in 1929, and an epidemic of brown spot fungus in 2000.

Perique

Perhaps the most strongly-flavored of all tobaccos is the Perique, from Saint James Parish, Louisiana. When the Acadians made their way into this region in 1755, the Choctaw and Chickasaw tribes were cultivating a variety of tobacco with a distinctive flavor. A farmer called Pierre Chenet is credited with first turning this local tobacco into the Perique in 1824 through the technique of pressure-fermentation.

The tobacco plants are manually kept suckerless, and pruned to exactly 12 leaves, through their early growth. In late June, when the leaves are a dark, rich green and the plants are 24-30 inches (600 to 750 mm) tall, the whole plant is harvested in the late evening and hung to dry in a sideless curing barn. Once the leaves have partially dried, but while still supple (usually less than 2 weeks in the barn), any remaining dirt is removed and the leaves are moistened with water and stemmed by hand. The leaves are then rolled into "torquettes" of approximately 1 pound (450 g) and packed into hickory whiskey barrels. The tobacco is then kept under pressure using oak blocks and massive screw jacks, forcing nearly all the air out of the still-moist leaves. Approximately once a month, the pressure is released, and each of the torquettes is "worked" by hand to permit a little air back into the tobacco. After a year of this treatment, the Perique is ready for consumption, although it may be kept fresh under pressure for many years. Extended exposure to air degrades the particular character of the Perique. The finished tobacco is dark brown, nearly black, very moist with a fruity, slightly vinegary aroma.

Considered the truffle of pipe tobaccos, the Perique is used as a component of many blended pipe tobaccos, but is too strong to be smoked pure. At one time, the freshly moist Perique was also chewed, but none is now sold for this purpose. Less than 16 acres (65,000 m^2) of this crop remain in cultivation, most by a single farmer called Percy Martin, in Grande Pointe, Louisiana. For reasons unknown, the particular flavor and character of the Perique can only be acquired on a small triangle of Saint James Parish, less than 3 by 10 miles (5 by 16 km). Although at its peak, Saint James Parish was producing around 20 tons of the Perique a year, output is now merely a few barrelsful.

It is traditionally a pipe tobacco, and is still very popular with pipe-smokers, typically blended with pure Virginia to lend spice, strength, and coolness to the blend. Perique may

now also be found in the Perique cigarettes of Santa Fe Natural Tobacco Co., in an approximately 1 part to 5 blend with lighter tobaccos. A similar tobacco, based on pressure-fermented Kentucky tobacco is available by the name Acadian Green River Perique.

Oriental Tobacco

Oriental tobacco is a sun-cured, highly aromatic, small-leafed variety that is grown in Turkey, Greece, Bulgaria, and Macedonia. Oriental tobacco is frequently referred to as "Turkish tobacco", as these regions were all historically part of the Ottoman Empire. Many of the early brands of cigarettes were made mostly or entirely of Oriental tobacco; today, its main use is in blends of pipe and especially cigarette tobacco (a typical American cigarette is a blend of bright Virginia, burley and Oriental).

Tobacco products

Snuff

Snuff is a generic term for fine-ground smokeless tobacco products. Originally the term referred only to dry snuff, a fine tan dust popular mainly in the eighteenth century. This is often called "Scotch Snuff", a folk-etymology derivation of the scorching process used to dry the cured tobacco by the factory.

European (dry) snuff is intended to be sniffed up the nose. Snuff is not "snorted" due to the fact that snuff shouldn't get past the nose i.e.; into sinuses, throat or lungs. European snuff comes in several varieties: Plain, Toast (fine ground - very dry), "Medicated" (menthol, camphor, eucalyptus, etc.), Scented and Schmalzler (a German variety.) The major brand names of European snuff are: Bernards (Germany), Fribourg & Treyer (UK), Gawith (UK), Gawith Hoggarth (UK), Hedges (UK), Lotzbeck (Germany), McChrystal's (UK), Pöschl (Germany) and Wilsons of Sharrow (UK).

Snuff has even been found to be beneficial in some cases of hay fever due to the fact that the snuff may prevent allergens from getting to the mucus membrane within the nose. *American* snuff is much stronger, and is intended to be dipped. It comes in two varieties -- "sweet" and "salty". Until the early 20th century, snuff dipping was popular in the United States among rural people, who would often use sweet barkless twigs to apply it to their gums. Popular brands are Tube Rose and Navy.

The second, and more popular in North America, variety of snuff is moist snuff, or dipping tobacco. This practice is known as "dipping." In the Southern states, taking a "dip" of moist snuff is called "putting a rub in," the moist snuff in the mouth is known as a "rub." This is occasionally referred to as "snoose" in New England and the Midwest and is derived from the Scandinavian word for snuff, "snus". Like the word, the origins of moist snuff are Scandinavian, and the oldest American brands indicate that by their names. Snuff is also called a "ding" in New England (i.e. "Packing a ding"). American Moist snuff is made from dark fire-cured tobacco that is ground, sweetened, and aged by the factory. Prominent North American brands are Copenhagen, Skoal, Timber Wolf, Chisholm, Grizzly, and Kodiak. American moist snuff tends to be dipped.

Some modern smokeless tobacco brands, such as Kodiak, have an aggressive nicotine delivery. This is accomplished with a higher dose of nicotine than cigarettes, a high pH level (which helps nicotine enter the blood stream faster), and a high portion of unprotonated (free base) nicotine.

It has been suggested by The Economist magazine that the ban on smoking tobacco indoors in some areas, such as Britain and New York City, may lead to a resurgence in the popularity of snuff as an alternative to tobacco smoking. Although the large-scale closure of British mines in the 1980s deprived the snuff industry of its major market since snuff became unfashionable (miners took snuff underground instead of smoking to avoid lethal explosions and fires), sales at Britain's largest snuff retailer have reportedly been rising at about 5% per year. [3]

Chewing tobacco

Chewing is one of the oldest ways of consuming tobacco leaves. Native Americans in both North and South America chewed the leaves of the plant, frequently mixed with lime. Modern chewing tobacco is produced in three forms: twist, plug, and scrap. A few manufacturers in the United Kingdom produce particularly strong twist tobacco meant for use in smoking pipes rather than chewing. These twists are not mixed with lime although they may be flavored with whisky, rum, cherry or other flavors common to pipe tobacco.

Twist is the oldest form. One to three high-quality leaves are braided and twisted into a rope while green, and then are cured in the same manner as other tobacco. Originally devised by sailors due to fire hazards of smoking at sea; and until recently this was done by farmers for their personal consumption in addition to other tobacco intended for sale. Modern twist is occasionally lightly sweetened. It is still sold commercially, but rarely seen outside of Appalachia. Popular brands are Mammoth Cave, Moore's Red Leaf, and Cumberland Gap. Users cut a piece off the twist and chew it, expectorating.

Plug chewing tobacco is made by pressing together cured tobacco leaves in a sweet (often molasses-based) syrup. Originally this was done by hand, but since the second half of the 19th century leaves were pressed between large tin sheets. The resulting sheet of tobacco is cut into plugs. Like twist, consumers sometimes cut, but more often bite off a piece of the plug to chew. Major brands are Days O Work and Cannonball.

Scrap, or looseleaf chewing tobacco, was originally the excess of plug manufacturing. It is sweetened like plug tobacco, but sold loose in bags rather than a plug. Looseleaf is by far the most popular form of chewing tobacco. Popular brands are Red Man, Beechnut, Mail Pouch and Southern Pride. Looseleaf chewing tobacco can also be dipped.

During the peak of popularity of chewing tobacco in the Western United States in the late 19th century, spittoons were a common device for users to spit into.

Snus

Swedish snus is different in that it is made from steam-cured tobacco, rather than fire-cured, and its health effects are markedly different, with epidemiological studies showing

dramatically lower rates of cancer and other tobacco-related health problems than cigarettes, American "Chewing Tobacco", Indian Gutka or African varieties. Prominent Swedish brands are Swedish Match, Ettan, and Tre Ankare. In the Scandinavian countries, moist snuff comes either in loose powder form, to be pressed into a small ball or ovoid either by hand or with the use of a special tool. It is sometimes packaged in small bags, suitable for placing inside the upper lip, called "portion snuff". In the United States, the Skoal brand of moist snuff distributes a similar product, packed with standard american moist snuff, often flavored with fruits or liquors; these small bags are called "Skoal Bandits." These small bags keep the loose tobacco from becoming lodged between the user's teeth; they also generate less spittle when in contact with mucous membranes inside the mouth which extends the usage time of the tobacco product.

Since it is not smoked, snuff in general generates less of the nitrosamines and other carcinogens in the tar that forms from the partially anaerobic reactions in the smoldering smoked tobacco. The steam curing of snus rather than fire-curing or flue-curing of other smokeless tobaccos has been demonstrated to generate even fewer of such compounds than other varieties of snuff; 2.8 parts per mil for Ettan brand compared to as high as 127.9 parts per mil in American brands, according to a study by the State of Massachusetts Health Department. It is hypothesized that the widespread use of snus by Swedish men (estimated at 30% of Swedish men, possibly because it is much cheaper than cigarettes), displacing tobacco smoking and other varieties of snuff, is responsible for the incidence of tobacco-related mortality in men being significantly lower in Sweden than any other European country. In contrast, since women are much less likely to use snus, their rate of tobacco-related deaths in Sweden is similar to that in other European countries. Snus is clearly less harmful than other tobacco products; according to Kenneth Warner, director of the University of Michigan Tobacco Research Network,

"The Swedish government has studied this stuff to death, and to date, there is no compelling evidence that it has any adverse health consequences. ... Whatever they eventually find out, it is dramatically less dangerous than smoking."

Public health researchers maintain that, nevertheless, even the low nitrosamine levels in snus cannot be completely risk free, but snus proponents maintain that inasmuch as snus is used as a substitute for smoking or a means to quit smoking, the net overall effect is positive, similar to the effect of nicotine patches, for instance. Snus is banned in the European Union countries outside of Sweden (regular snus, not portion, is allowed in Denmark and snus is also becoming a regular among Norwegians, as cigarettes are seen by Norwegian popular culture as untrendy and much more unhealthy than snus). Although this is officially for health reasons, it is widely regarded, in fact, as being for economic reasons, since other smokeless tobacco products (mainly from India) associated with much greater risk to health are sold too.

Although it lacks the carcinogenicity of high levels of nitrosamines, however, any harmful effects of nicotine will still be seen with snus usage. Current research concentrates on nicotine's effect on the circulatory system and on the pancreas.

On June 11, 2006, Reynolds Tobacco announced that it would be test marketing Camel brand snus in Portland, Oregon and Austin, Texas by the end of the month. The product

would be manufactured in Sweden, in conjunction with British American Tobacco, manufacturers of BAT snus. [6] gawith apricot snuff

Gutka

Gutka is a tobacco product manufactured and used mainly in India. It contains sweeteners, food coloring and paan flavorings . It is used by constantly chewing without swallowing the juices and then spitting the juices out once the mouth is full of the liquid. This results in the walls of most public buildings to be covered in red stains called pichkari, especially in areas where males from lower income levels congregate.

Creamy snuff

Creamy snuff is a tobacco paste, consisting of tobacco, clove oil, glycerin, spearmint, menthol, and camphor, and sold in a toothpaste tube. It is marketed mainly to women in India, and is known by the brand names Ipco (made by Asha Industries), Denobac, Tona, Ganesh. It is locally known as "mishri" in some parts of Maharashtra. According to the U.S NIH-sponsored 2002 Smokeless Tobacco Fact Sheet, it is marketed as a dentifrice. The same factsheet also mentions that it is "often used to clean teeth. The manufacturer recommends letting the paste linger in the mouth before rinsing."

Tobacco water

Tobacco water is a traditional organic insecticide used in domestic gardening. Tobacco dust can be used similarly.

It is produced by boiling strong tobacco in water, or by steeping the tobacco in water for a longer period. When cooled the mixture can be applied as a spray, or 'painted' on to the leaves of garden plants, where it will prove deadly to insects.

Basque angulero fishermen kill immature eels (elvers) in an infusion of tobacco leaves before parboiling them in salty water for transportation to market as angulas, a seasonal delicacy.[7]

Curare

Curare is a common name for various dart poisons originating from South America. The three main types, or famillies of curare are: the tubocurare (also known as tube or bamboo curare, because of its packing into hollow bamboo tubes; main toxin is D-tubocurarine), the calebas curare (also called "gourd curare" by older british classifications, beeing packed into hollow gourds; main toxins are alloferine and toxiferine) and the pot curare (packed in terracota pots; main toxins are protocurarine, protocurine, and protocuridine). Of these

three families, some formulas belonging to the calebas curare are the most toxic, relative to their LD***50*** values.

The most known and historically (because of its medical applications) important toxin is however the D-tubocurarine. It was introduced into anesthesiology in early 1940s as a muscle relaxant for surgery. It is important to know, that curares are active (i.e. toxic or muscle relaxing, dependant on the intention of their use) only if given/applied parenterally, that is, by an injection, or direct wound contamination by poisoned dart/arrow tip. Upon ingestion (per os), curares are inactive. This is crucial, because the native tribes use curares mainly for hunting purposes, thus the poisoned prey must be innoxious upon eating. In medicine, curare has been superseded by a number of curare-like agents (examples are succinylcholine, also called suxamethonium, and pancuronium, an alkaloid-like substance with steroidal skeleton in its molecule), that have a similar pharmacodynamic profile but with fewer side effects.

Curare is an example of a non-depolarizing muscle relaxant which blocks the nicotinic receptors, one of the two types of cholinergic (acetylcholine) receptors on the post synaptic membrane of the neuromuscular junction.

Curare has also been used historically as a paralyzing poison by South American indigenous people. The prey is killed by asphyxiation as the respiratory muscles are unable to contract resulting in apnea.

Curare and anaesthesia

Muscle relaxants are used in modern anaesthesia for many reasons, such as providing optimal operating conditions and facilitating intubation of the trachea. Before muscle relaxants, anaesthesiologists needed to use larger doses of the anaesthetic agent, such as ether or cyclopropane to achieve these aims. Such deep anaesthesia risked killing patients that were elderly or had heart conditions.

The source of curare in the Amazon was first researched by Richard Evans Schultes in 1941. Since the 1930s, it was being used in hospitals as a muscle relaxant. He discovered that different types of curare called for as many as 15 ingredients, and in time helped to identify more than 70 species that produced the drug [1].

On January 23, 1942, Dr. Harold Griffith and Dr. Enid Johnson gave a synthetic preparation of curare (Intracostin) to a patient undergoing an appendectomy (to supplement conventional anaesthesia). Modern anaesthetists have at their disposal a variety of muscle relaxants for use as a standard component of anaesthesia.

The ability to produce muscle relaxation independently from anaesthesia has permitted anaesthesiologists to adjust the two effects as needed to ensure that their patients are safely unconscious and sufficiently relaxed to permit surgery. However, it has also made possible anaesthesia awareness, a condition in which, through error or accident, a patient remains fully conscious and sensitive to pain during surgery, but is unable to move and thus unable to alert attending staff to their state of awareness.

Plants from which primary components of curare can be extracted

- Strychnos toxifera
Chondrodendron tomentosum

Anticoagulant

An *anticoagulant* is a substance that prevents coagulation; that is, it stops blood from clotting. A group of pharmaceuticals called anticoagulants can be used in vivo as a medication for thrombotic disorders. Some chemical compounds are used in medical equipment, such as test tubes, blood transfusion bags, and renal dialysis equipment..

As medications

Anticoagulants are given to people to stop thrombosis (blood clotting inappropriately in the blood vessels). This is useful in primary and secondary prevention of deep vein thrombosis, pulmonary embolism, myocardial infarctions and strokes in those who are predisposed.

Vitamin K antagonists

The oral anticoagulants are a class of pharmaceuticals that act by antagonizing the effects of vitamin K. It is important to note that they take at least 48 to 72 hours for the anticoagulant effect to develop fully. In cases when an immediate effect is required, heparin must be given concomitantly. Generally, these anticoagulants are used to treat patients with deep-vein thrombosis (DVT), pulmonary embolism, atrial fibrillation, and mechanical prosthetic heart valves.

These oral anticoagulants are used widely as poisons for mammalian pests, especially rodents. (For details, see rodenticide and warfarin.)

The most important oral anticoagulants are:

- Warfarin (Coumadin). This is the main agent used in the U.S. and UK
- Acenocoumarol and phenprocoumon This is used more commonly outside the U.S. and the UK
- Phenindione

Heparin and derivative substances

Heparin is a biological substance, usually made from pig intestines. It works by activating antithrombin III, which blocks thrombin from clotting blood. Heparin can be used in vivo (by injection), and also in vitro to prevent blood or plasma clotting in medical devices. Vacutainer brand test tubes containing heparin are usually colored green.

Low molecular weight heparin is a more highly processed product that is useful as it does not require monitoring of the APTT coagulation parameter (it has more predictable plasma levels) and has less side effects.

Fondaparinux is a synthetic sugar composed of the five sugars (pentasaccharide) in heparin that bind to antithrombin. It is a smaller molecule than low molecular weight heparin.

Direct thrombin inhibitors

Another type of anticoagulant is the direct thrombin inhibitors. Current members of this class include argatroban, lepirudin, and bivalirudin. An oral direct thrombin inhibitor, ximelagatran (Exanta®) may replace warfarin for some indications. It is awaiting Food and Drug Administration (FDA) approval.

Anticoagulants outside the body

Laboratory instruments, test tubes, blood transfusion bags, and medical and surgical equipment will get clogged up and become nonoperational if blood is allowed to clot. Chemicals can be added to stop blood clotting. Apart from heparin, most of these chemicals work by binding calcium ions, preventing the coagulation proteins from using them.

- EDTA is denoted by mauve or purple caps on Vacutainer brand test tubes. This chemical strongly and irreversibly binds calcium. It is in a powdered form.

  Citrate is usually in blue Vacutainer tube. It is in liquid form in the tube and is used for coagulation tests, as well as in blood transfusion bags. It gets rid of the calcium, but not as strongly as EDTA. Correct proportion of this anticoagulant to blood is crucial because of the dilution. It can be in the form of sodium citrate or ACD.

  Oxalate has a similar mechanism to citrate. It is the anticoagulant used in fluoride (grey top) tubes.

Therapeutic considerations

Routes i.v., s.c.

Heparin is a highly sulfated glycosaminoglycan widely used as an injectable anticoagulant. It is also used to form an inner anticoagulant surface on various experimental and medical devices such as test tubes and renal dialysis machines. Pharmaceutical grade heparin is commonly derived from mucosal tissues of slaughtered meat animals such as porcine intestine or bovine lung.[1]

Heparin structure

Native heparin is a polymer with a molecular weight ranging from 3 kDa to 40 kDa although the average molecular weight of most commercial heparin preparations is in the range of 12 kDa to 15 kDa. Heparin is a member of the glycosaminoglycan family of carbohydrates (which includes the closely related molecule heparan sulfate) and consists of a variably sulfated repeating disaccharide unit. The main disaccharide units that occur in heparin are shown below. The most common disaccharide unit is composed of a 2-O-sulfated iduronic acid and 6-O-sulfated, N-sulfated glucosamine, IdoA(2S)-GlcNS(6S). For example this makes up 85% of heparins from beef lung and about 75% of those from porcine intestinal mucosa. Not shown below are the rare disaccaharides containing a 3-O-sulfated glucosamine (GlcNS(3S,6S) or a free amine group (GlcNH3+). Under physiological conditions the ester and amide sulfate groups are deprotonated and attract positively charged counterions to form a heparin salt. It is in this form that heparin is usually administered as an anticoagulant.

Abbreviations

- *GlcA* = ²-L-glucuronic acid
- *IdoA* = ±-L-iduronic acid
- *IdoA(2S)* = 2-O-sulfo-±-L-iduronic acid
- *GlcNAc* = 2-deoxy-2-acetamido-±-D-glucopyranosyl
- *GlcNS* = 2-deoxy-2-sulfamido-±-D-glucopyranosyl
- *GlcNS(6S)* = 2-deoxy-2-sulfamido-±-D-glucopyranosyl-6-O-sulfate

Three-dimensional structure

The three dimensional structure of heparin is complicated by the fact that iduronic acid may be present in either of two low energy conformations when internally positioned within an oligosaccharide. The conformational equilibrium being influenced by sulfation state of adjacent glucosamine sugars.[2] Nevertheless the solution structure of a heparin dodecasacchride composed solely of six GlcNS(6S)-IdoA(2S) repeat units has been determined using a combination of NMR spectroscopy and molecular modelling techniques.[3] Two models were constructed one in which all IdoA(2S) were in the 2S0 conformation (A and B below) and one in which they are in the 1C4 conformation (C and D below). However there is no evidence to suggest changes between these conformations occurs in a concerted fashion. These models correspond to the protein data bank code 1HPN

In these models heparin adopts a helical conformation, the rotation of which places clusters of sulfate groups at regular intervals of about 17 angstroms (1.7 nm) on either side of the helical axis.

Medical use

Heparin acts as an anticoagulant, preventing the formation of clots and extension of existing clots within the blood. While heparin does not break down clots that have already formed, it allows the body's natural clot lysis mechanisms to work normally to break down clots that have already formed. Heparin is used for anticoagulation for the following conditions:

- Acute coronary syndrome, e.g., myocardial infarction

Atrial fibrillation

Deep-vein thrombosis and pulmonary embolism.

History

Heparin is one of the oldest drugs currently still in widespread clinical use. As it was discovered in 1916, its introduction predates the establishment of the United States Food and Drug Administration.[4] It was originally isolated from liver cells, hence its name (hepar or "·À±Á" is Greek for "liver"). Scientists were looking for an anticoagulant that could work safely in humans, and Jay McLean, a second-year medical student from Johns Hopkins University working under the guidance of William Henry Howell, found a compound extracted from liver that acted as an anticoagulant.

Administration

Heparin is given parenterally; it is digested when taken by mouth. It can be injected intravenously or subcutaneously (under the skin). Intramuscular injections (into muscle) are avoided because of the potential for forming hematomas. Because of its short biologic half-life of approximately one hour, heparin must be given frequently or as a continuous infusion.

If long-term anticoagulation is required, heparin is often only used to commence anticoagulation therapy until the oral anticoagulant warfarin takes effect.

Adverse reactions

A serious side-effect of heparin is heparin-induced thrombocytopenia (HIT syndrome). HITS is caused by an immunological reaction that makes platelets aggregate within the blood vessels, thereby using up coagulation factors. Formation of platelet clots can lead to thrombosis, while the loss of coagulation factors and platelets may result in bleeding. HITS can (rarely) occur shortly after heparin is given, but also when a person has been on heparin for a long while. Immunologic tests are available for the diagnosis of HITS. There is also a benign form of thrombocytopenia associated with early heparin use which resolves without stopping heparin.

Other side effects include alopecia and osteoporosis.

As with many drugs, overdoses of Heparin can be fatal. In September 2006, Heparin received worldwide publicity when 3 prematurely-born infants died after they were mistakenly given adult-sized doses of Heparin at an Indianapolis hospital.[5]

Treatment of overdose

In case of overdose, protamine sulfate can be given to counteract the action of heparin.

Mechanism of action

Heparin is a naturally occurring anticoagulant produced by basophils and mast cells. [6] Heparin binds to the enzyme inhibitor antithrombin III (AT-III) causing a conformational change which results in its active site being exposed. The activated AT-III then inactivates thrombin and other proteases involved in blood clotting, most notably factor Xa. The rate of inactivation of these proteases by AT-III increases 1000-fold due to the binding of heparin.[7]

AT-III binds to a specific pentasaccharide sulfation sequence contained within the heparin polymer

GlcNAc/NS(6S)-GlcA-GlcNS(3S,6S)-IdoA(2S)-GlcNS(6S)

The conformational change in AT-III on heparin binding mediates its inhibition of factor Xa. For thrombin inhibition however, thrombin must also bind to the heparin polymer at a site proximal to the pentasacchride. The formation of a ternary complex between AT-III, thrombin and heparin results in the inactivation of thrombin. For this reason heparin's activity against thrombin is size dependent, the ternary complex requiring at least 18 saccharide units for efficient formation.[8] In contrast anti factor Xa activity only requires the pentasacchride binding site.

This size difference has led to the development of low molecular weight heparins and more recently to fondaparinux (a synthetic pentasacchride identical in structure to the AT-III binding pentasacchride) as pharmaceutical anticoagulants. These products target anti

factor Xa activity rather than anti thrombin (IIa) activity with the aim of facilitating a more subtle regulation of coagulation and an improved therapeutic index.

With these fractioned heparin alternatives, there is a reduced risk of osteoporosis and heparin-induced thrombocytopenia (HIT). Monitoring of the APTT is also not required and indeed does not reflect the anticoagulant effect, as APTT is insensitive to alterations in factor Xa.

Danaparoid, a mixture of heparan sulfate, dermatan sulfate and chondroitin sulfate can be used as an anticoagulant in patients who have developed HIT. Because danaparoid does not contain heparin or heparin fragments cross-reactivity of danaparoid with heparin-induced antibodies is reported as less than 10% (see here)

The effects of heparin are measured in the lab by the partial thromboplastin time (aPTT), (the time it takes the blood plasma to clot).

Heparin's exact physiological role is still unclear, because blood anti-coagulation is mostly achieved by endothelial cell-derived heparan sulfate proteoglycans.[9]

Heparin gel

Heparin gel (topical) may sometimes be used to treat sports injuries. It is known that the diprotonated form of histamine binds site specifically to heparin.[10] The release of histamine from mast cells at a site of tissue injury contributes to an inflammatory response. The rationale behind the use of such topical gels may be to block the activity of released histamine and so help to reduce inflammation.

Other uses/information

- Test tubes, Vacutainers, and capillary tubes that use the lithium salt of heparin (lithium heparin) as an anticoagulant are usually marked with green stickers and green tops. Heparin has the advantage over EDTA as an anticoagulant, as it does not affect levels of ions (such as calcium). Heparin can interfere with some immunoassays, however. As lithium heparin is usually used, a person's lithium levels cannot be obtained from these tubes; for this purpose, royal-blue topped Vacutainers containing sodium heparin are used.
- Heparin-coated blood oxygenators are available for use in heart-lung machines. Among other things, these specialized oxygenators are though to improve overall biocompatibility and host homeostasis by providing characteristics similar to native endothelium.
- Common diagnostic procedures require PCR amplification of a patient's DNA, which is easily extracted from white blood cells treated with heparin. This poses a potential problem, since heparin may be extracted along with the DNA, and it has been found to interfere with the PCR reaction at levels as low as 0.002 U in a 50 ¼L reaction mixture.[11]

Routes Oral

Warfarin (also known under the brand names of *Coumadin*®, *Jantoven*®, *Marevan*®, and *Waran*®) is an anticoagulant medication that is administered orally or, very rarely, by injection. It is used for the prophylaxis of thrombosis and embolism in many disorders. Its activity has to be monitored by frequent blood testing for the international normalized ratio (INR). It is named for the Wisconsin Alumni Research Foundation.

Warfarin is a synthetic derivative of coumarin, a chemical found naturally in many plants, notably woodruff (Galium odoratum, Rubiaceae), and at lower levels in licorice, lavender and various other species. Warfarin was originally developed as a rat poison, but it is no longer used for that purpose as modern poisons are much more potent and toxic (e.g. brodifacoum). However, warfarin and contemporary rodenticides belong to the same class of drugs (coumarins) and both decrease blood coagulation by interfering with vitamin K metabolism.

Mechanism of action

Warfarin inhibits the synthesis of biologically active forms of the vitamin K-dependent clotting factors: II, VII, IX and X, as well as the regulatory factors protein C, protein S and protein Z. Other proteins not involved in blood clotting, such as osteocalcin, or matrix Gla protein, may also be affected.

The precursors of these factors require carboxylation of their glutamic acid residues to allow the coagulation factors to bind to phospholipid surfaces inside blood vessels, on the vascular endothelium. This enzyme that carries out the carboxylation of glutamic acid is the gamma-glutamyl carboxylase. The carboxylation reaction will only proceed if the carboxylase enzyme is able to convert a reduced form of Vitamin K (Vitamin K hydroquinone) to vitamin K epoxide at the same time. The Vitamin K epoxide is in turn recycled back to Vitamin K and Vitamin K hydroquinone by another enzyme, the vitamin K epoxide reductase (VKOR). Warfarin inhibits epoxide reductase[1] (specifically the VKORC1 subunit[2][3]), thereby diminishing available vitamin K and Vitamin K hydroqunone in the tissues, which inhibits the carboxylation activity of the glutamyl carboxylase. When this occurs, the coagulation factors are no longer carboxylated at certain glutamic acid residues, and are incapable of binding to the endothelial surface of blood vessels, and are thus biologically inactive. As the body stores of previously-produced active factors degrade (over several days) and are replaced by inactive factors, the anticoagulation effect becomes apparent. The coagulation factors are produced, but have decreased functionality due to undercarboxylation; they are collectively referred to as PIVKAs (proteins induced [by] vitamin K absence/antagonism). Hence, the effect of warfarin is to diminish blood clotting in the patient.

Uses

Medical use

Warfarin is prescribed to people with an increased tendency for thrombosis or as prophylaxis in those individuals who have already formed a blood clot (thrombus) which required treatment. This can help prevent formation of future blood clots and help reduce the risk of embolism (migration of a thrombus to a spot where it blocks blood supply to a vital organ). Common clinical indications for warfarin use are atrial fibrillation, artificial heart valves, deep venous thrombosis and pulmonary embolism.[4]

Dosing of warfarin is complicated by the fact that it is known to interact with many commonly used medications and other chemicals that may be present in appreciable quantities in food. These interactions may enhance or reduce warfarin's anticoagulation effect. Many commonly used antibiotics, such as metronidazole or the macrolides, will greatly increase the effect of warfarin by reducing the metabolism of warfarin in the body. Other broad-spectrum antibiotics can reduce the amount of the normal bacterial flora in the bowel, which make significant quantities of Vitamin K, thus potentiating the effect of warfarin. In addition, food that contains large quantities of Vitamin K will reduce the warfarin effect; and medical conditions such as hypo- or hyperthyroidism will alter the rate of breakdown of the clotting factors.

Therefore, in order to optimise the therapeutic effect without risking dangerous side effects, such as bleeding, close monitoring of the degree of anticoagulation is required by blood testing (INR). Initially, checking may be as often as twice a week; the intervals can be lengthened if the patient manages stable therapeutic INR levels on an unchanged warfarin dose.

When initiating warfarin therapy ("warfarinisation"), the doctor will decide how strong the anticoagulant therapy needs to be. The target INR level will vary from case to case dependent upon the clinical indicators, but tends to be 2-3 in most conditions.

The oral anticoagulant ximelagatran (Exanta®) was expected to replace warfarin to a large degree when introduced; however, reports of hepatotoxicity (liver damage) prompted its manufacturer to withdraw it from further development. Other drugs offering the efficacy of warfarin without a need for monitoring, such as dabigatran and rivaroxaban, are under development.

Pesticide use

Coumarins, a class of drugs of which warfarin is a member, are used as a rodenticide for controlling rats and mice in residential, industrial, and agricultural areas. The active ingredient in rat poison is brodifacoum, which is sometimes referred to as a super-warfarin, because it is longer acting than the drug warfarin. It is both odorless and tasteless. It is effective when mixed with food bait, because the rodents will return to the bait and continue to feed over a period of days, until a lethal dose is accumulated (considered to be 1 mg/kg b.w./day over four to five days for warfarin; for brodifacoum, no reliable cumulative toxicity datas are available as of time, but it could be concluded, given the similarity with other 4-hydroxycoumarin derivatives, that these would be in order of tens of μg/kg b.w./day for periods of 2-10 days). It may also be mixed with talc and used as a tracking powder, which accumulates on the animal's skin and fur, and is subsequently consumed during grooming. The use as rat poison is now declining because many rat populations have developed resistance to warfarin.

The LD50 is 50–500 mg/kg. The IDLH value is 100mg/m^3 (warfarin; various species). LD***50***(mouse, oral) = 0.40 mg/kg; (rat, oral) = 0.27 mg/kg (brodifacoum). The IDLH value for brodifacoum is not defined, but given the toxicity of brodifacoum, it would be substantialy lower, perhaps less than 1/100 of the warfarin value, i.e. <1 mg/m^3.

Side-effects

The only common side-effect of warfarin is hemorrhage (bleeding). The risk of severe bleeding is small but definite (1-2% annually) and any benefit needs to outweigh this risk when warfarin is considered as a therapeutic measure. Risk of bleeding is augmented if the INR is out of range (due to accidental or deliberate overdose or due to interactions), and may cause hemoptysis (coughing up blood), excessive bruising, bleeding from nose or gums, or blood in urine or stool.

A feared (but rare) complication of warfarin is warfarin necrosis, which occurs more frequently shortly after commencing treatment in patients with a deficiency of protein C. Protein C is an innate anticoagulant that, like the procoagulant factors that warfarin inhibits, requires vitamin K-dependent carboxylation for its activity. Since warfarin initially decreases protein C levels faster than the coagulation factors, it can paradoxically increase the blood's tendency to coagulate when treatment is first begun (many patients when starting on warfarin are given heparin in parallel to combat this), leading to massive

thrombosis with skin necrosis and gangrene of limbs. Its natural counterpart, purpura fulminans, occurs in children who are homozygous for protein C mutations.

Pharmacology

Pharmacokinetics and antagonism

Warfarin consists of a racemic mixture of two active optical isomers - R and S forms - each of which is cleared by different pathways. S-warfarin has five times the potency of the R-isomer with respect to Vitamin K antagonism.[4]

Warfarin is slower acting than the common anticoagulant heparin, though it has a number of advantages. Heparin must be given by injection, while warfarin is available orally. Warfarin has a long half-life and need only be given once a day. Heparin can also cause a prothrombotic condition, heparin-induced thrombocytopenia (an antibody-mediated decrease in platelet levels), which paradoxically increases the risk for thrombosis. Warfarin's long half life, on the other hand, means it often takes several days to reach therapeutic effect. Furthermore, if given initially without additional anticoagulant cover, it can paradoxically increase thrombosis risk. For these main reasons, hospitalised patients are usually given heparin initially, and are then moved on to warfarin.

Warfarin can be reversed with vitamin K, or for rapid reversal (e.g. in case of severe bleeding), with fresh frozen plasma but this treatment is being replaced by use of prothrombin complex concentrate.

Pharmacogenomics

Warfarin activity is determined partially by genetic factors. Polymorphisms in the VKORC1 gene explain 25% of the dose variation between patients: particular mutations make VKORC1 less susceptible to suppression by warfarin.[3][5] CYP2C9 polymorphisms explain another 10%.[5] VKORC1 polymorphisms also explain why African Americans are relatively resistant to warfarin, while Asian Americans are more sensitive.[5]*Small Text*

Loading regimens

Because of warfarin's poorly predictable pharmacokinetics, several researchers have proposed algorithms for commencing warfarin treatment. For urgent anticoagulation, the Fennerty regimen[6] is used commonly, while for "routine" (low-risk) anticoagulation, the Tait regimen[7] is more popular.

Interactions and contraindications

There are many drug-drug interactions with warfarin, and its metabolism varies greatly between patients. Some foodstuffs have also been reported to interact with warfarin[8] This makes finding the correct dosage difficult, and accentuates the need of monitoring; when initiating a medication that is known to interact with warfarin (e.g. amiodarone), INR checks are increased or dosages adjusted until a new ideal dosage is found.

Warfarin cannot be given to pregnant women, especially in the first trimester, as it is a teratogen (it causes deformations of the face and bones). During the third trimester, antepartum hemorrhage can occur. Instead of warfarin, low molecular weight heparin is generally used.

Excessive use of alcohol is also known to affect the metabolism of warfarin, although moderate drinking usually has little or no effect on the INR value. Patients suffering from liver damage or alcoholism are usually treated with heparin injections instead.

Warfarin also interacts with the following herbs: [9]

- Ginkgo (a.k.a. Ginkgo Biloba), which is commonly used to increase brain blood flow, prevent dementia, and improve memory. However, ginkgo may increase blood pressure, and may increase bleeding, especially in people already taking certain anti-clotting medications such as warfarin.
- St. John's Wort is commonly used to help with mild to moderate depression. However, it may prolong the effects of certain anesthetic drugs and reduce the effects oral contraceptives and anti-organ transplant rejection medications, and interfere with warfarin.
- Ginseng is commonly used to help with fatigue and weakness. However, ginseng may increase blood pressure and heart rate and may increase bleeding, especially in people already taking certain anti-clotting medications such as warfarin.
- Garlic (as a supplement, not in the diet) is commonly used to help lower high cholesterol levels, high triglycerides, and high blood pressure. However, may increase bleeding especially in people already taking certain anti-clotting medications such as warfarin.
- Ginger is commonly used to help nausea and poor digestion. However, it may increase bleeding, especially in patients already taking certain anti-clotting medications such as warfarin.

History

The early 1920s saw the outbreak of a previously unrecognized disease of cattle in the northern United States and Canada. Cattle would die of uncontrollable bleeding from very minor injuries, or sometimes drop dead of internal hemorrhage with no external signs of injury. In 1921, Frank Schofield, a Canadian veterinarian, determined that the cattle were ingesting moldy silage made from sweet clover that functioned as a potent anticoagulant.[10] In 1929, North Dakota veterinarian Dr L.M. Roderick demonstrated that the condition was due to a lack of functioning prothrombin.[11]

The identity of the anticoagulant substance in moldy sweet clover remained a mystery until 1940 when Karl Paul Link and his student Harold Campbell, chemists working at the University of Wisconsin, determined that it was the coumarin derivative 4-hydroxycoumarin.[12] Over the next few years, numerous similar chemicals were found to have the same anticoagulant properties. The first of these to be widely commericialized was dicoumarol, patented in 1941. Link continued working on developing more potent coumarin-based anticoagulants for use as rodent poisons, resulting in warfarin in 1948. (The

name warfarin stems from the acronym WARF, for Wisconsin Alumni Research Foundation + the ending -arin indicating its link with coumarin. Warfarin was first registered for use as a rodenticide in the US in 1952; although it was developed by Link, the WARF financially supported the research and was granted the patent.

The exact mechanism of action remained unknown until it was demonstrated, in 1978, that warfarin inhibited epoxide reductase and hence interfered with vitamin K metabolism.[1]

After an incident in 1951, where a naval enlisted man unsuccessfully attempted suicide with warfarin and recovered fully, studies began in the use of warfarin as a therapeutic anticoagulant. It was found to be generally superior to dicoumarol, and in 1954 was approved for medical use in humans. A famous early patient prescribed warfarin was Dwight Eisenhower, president of the USA, subsequent to his heart attack in 1955.

A 2003 theory posits that warfarin was used by a conspiracy of Lavrenty Beria, Nikita Khrushchev and others to poison Soviet leader Joseph Stalin. Warfarin is tasteless and colorless, and produces symptoms similar to those that Stalin exhibited.[13]

Other coumarins

In some countries, other coumarins are used instead of warfarin, such as acenocoumarol and phenprocoumon. These have a shorter (acenocoumarol) or longer (phenprocoumon) half-life, and are not completely interchangeable with warfarin.

Anticonvulsants

The *anticonvulsants*, sometimes also called *antiepileptics*, belong to a diverse group of pharmaceuticals used in prevention of the occurrence of epileptic seizures. The goal of an anticonvulsant is to suppress the rapid and excessive firing of neurons that start a seizure. Failing this, a good anticonvulsant would prevent the spread of the seizure within the brain and offer protection against possible excitotoxic effects that may result in brain damage. An excellent anticonvulsant would have few serious side effects. However, no such drug exists.

Many anticonvulsants block Sodium (Na+) channels, Calcium (Ca2+) channels, AMPA receptors or NMDA receptors. Some anticonvulsants inhibit the metabolism of GABA or increase its release.

In the following list, the dates in parentheses are the earliest approved use of the drug.

Aldehydes

- Paraldehyde (1882). One of the earliest anticonvulsants. Still used to treat status epilepticus, particularly where there are no resuscitation facilities.

Aromatic allylic alcohols

- Stiripentol (2001 - limited availability). Indicated for the treatment of severe myoclonic epilepsy in infancy (SMEI).

Barbiturates

Main article: Barbiturates

Barbiturates are drugs that act as central nervous system (CNS) depressants, and by virtue of this they produce a wide spectrum of effects, from mild sedation to anesthesia. The following are classified as anticonvulsants:

- Phenobarbital (1912). See also the related drug primidone.
- Methylphenobarbital (1935). Known as mephobarbital in the US. No longer marketed in the UK
- Metharbital (1952). No longer marketed in the UK or US.
- Barbexaclone (1982). Only available in some European countries.

Phenobarbital was the main anticonvulsant from 1912 till the development of phenytoin in 1938. Today, phenobarbital is rarely used to treat epilepsy in new patients since there are other effective drugs that are less sedating. Phenobarbital sodium injection can be used to stop acute convulsions or status epilepticus, but a benzodiazepine such as lorazepam, diazepam or midazolam is usually tried first. Other barbiturates only have an anticonvulsant effect at anaesthetic doses.

Benzodiazepines

Main article: Benzodiazepines

The benzodiazepines are a class of drugs with hypnotic, anxiolytic, anticonvulsive, amnestic and muscle relaxant properties. The relative strength of each of these properties in any given benzodiazepine varies greatly and influences the indications for which it is prescribed. Long-term use can be problematic due to the development of tolerance and dependency. Of the many drugs in this class, only a few are used to treat epilepsy:

- Clobazam (1979). Notably used on a short-term basis around menstruation in women with catamenial epilepsy. Clonazepam (1974). Clorazepate (1972).

The following benzodiazepines are used to treat status epilepticus:

- Diazepam (1963). Can be given rectally by trained care-givers.
- Midazolam (N/A). Increasingly being used as an alternative to diazepam. This water-soluble drug is squirted into the side of the mouth but not swallowed. It is rapidly absorbed by the buccal mucosa.
- Lorazepam (1972). Given by injection in hospital.

Bromides

- Potassium bromide (1857). The earliest effective treatment for epilepsy. There would not be a better drug for epilepsy until phenobarbital in 1912. It is still used as an anticonvulsant for dogs and cats.

Carbamates

- Felbamate (1993). This effective anticonvulsant has had its usage severely restricted due to rare but life-threatening side effects.

Carboxamides

Main article: Carboxamides

The following are carboxamides:

- Carbamazepine (1965). A popular anticonvulsant that is available in generic formulations. Oxcarbazepine (1990). A derivative of carbamazepine that has similar efficacy but is better tolerated.

Fatty acids

The following are fatty-acids:

- The valproates — valproic acid, sodium valproate, and divalproex sodium (1978).

Vigabatrin (1989).
Progabide
Tiagabine (1997).

Vigabatrin and progabide are also analogs of GABA.

Fructose derivatives

- Topiramate (1995).

Gaba analogs

- Gabapentin (1993).
Pregabalin (2004).

Hydantoins

The following are hydantoins:
- Ethotoin (1957).
Phenytoin (1938).
Mephenytoin
Fosphenytoin (1996).

Oxazolidinediones

The following are oxazolidinediones:
- Paramethadione
Trimethadione (1946).
Ethadione

Propionates

- Beclamide

Pyrimidinediones

- Primidone (1952).

Pyrrolidines

- Brivaracetam
Levetiracetam (1999).
Seletracetam

Succinimides

The following are succinimides:

- Ethosuximide (1955).

Phensuximide
Mesuximide

Sulfonamides

Main article: Sulfonamides

- Acetazolamide (1953).

Sulthiame
Methazolamide
Zonisamide (1990).

Triazines

- Lamotrigine (1991).

Ureas

- Pheneturide

Phenacemide

Valproylamides (amide derivatives of valproate)

- Valpromide

Valnoctamide

Barbiturates

Barbiturates are drugs that act as central nervous system (CNS) depressants, and by virtue of this they produce a wide spectrum of effects, from mild sedation to anesthesia. Some are also used as anticonvulsants.

Barbiturates are believed to be GABA (gamma-aminobutyric acid) agonists, acting on the GABA-A receptor. GABA is the principal inhibitory neurotransmitter in the mammalian CNS.

Barbiturates are derivatives of barbituric acid.

Medical uses

Today barbiturates are infrequently used as anticonvulsants and for the induction of anesthesia. Benzodiazepines were made as safer barbiturate alternatives as they are virtually impossible to overdose and thus help thwart individuals with suicidal tendencies. Since the introduction of Diazepam in 1963, the first benzodiazepine prescibed for clinical

use, barbiturates have been gradually phased out from use. Some of the barbiturates available are:

- Amobarbital (Sodium Amytal; hypnotics)

Aprobarbital (hypnotic)
Butabarbital (hypnotics)
Butalbital (Fiorinal; sedative)
Hexobarbital (Sombulex; hypnotic/anesthetic)
Methylphenobarbital (Mebaral; antianxiety, anticonvulsant)
Pentobarbital (Nembutal; hypnotic)

- Phenobarbital (Luminal; hypnotic, sedative, anticonvulsant)
- Secobarbital (Seconal; hypnotic)

Sodium thiopental
Talbutal (Lotusate; hypnotic)
Thiobarbital (anesthetic)

Sometimes two or more barbiturates are combined in a single tablet or capsule; perhaps the most well-known of these combinations is Tuinal, which consists of amobarbital and secobarbital in equal proportions.

Recreational use

Barbiturates were very popular in the first half of the twentieth century. In moderate amounts, these drugs produce a state of intoxication that is remarkably similar to alcohol intoxication. Symptoms include slurred speech, loss of motor coordination, and impaired judgment. Depending on the dose, frequency, and duration of use, one can rapidly develop tolerance, physical dependence, and psychological dependence on barbiturates. With the development of tolerance, the margin of safety between the effective dose and the lethal dose becomes very narrow. That is, in order to obtain the same level of intoxication, the tolerant abuser may raise his or her dose to a level that may result in coma or death. Although many individuals have taken barbiturates therapeutically without harm, concern about the addiction potential (withdrawal symptoms can include tonic-clonic or grand mal seizures potentially leading to permanent disability or even death) of barbiturates and the ever-increasing number of fatalities associated with them led to the development of alternative medications, namely benzodiazepines. Today, fewer than 10 percent of all sedative/hypnotic prescriptions in the United States are for barbiturates.

Other non-therapeutical use

Barbiturates in high doses are used for physician-assisted suicide (PAS). In combination with a muscle relaxant, for euthanasia and for capital punishment by lethal injection.

History

- Dec 4, 1863 Barbituric acid is discovered by German researcher Adolf von Baeyer. His discovery came on the day of St. Barbara, the patron saint of chemistry, so he chose the name "barbiturate" as a combination of St. Barbara

and "urea". Another possible explanation is that he named the substance after his girlfriend Barbara.

- 1903 Barbital, the first medicinal barbiturate, is synthesized from barbituric acid by German scientists Emil Hermann Fischer and Joseph von Mering. It was marketed under the trade name Veronal.
- 1912 Phenobarbital is introduced under the trade name Luminal as a sedative-hypnotic.
- 1950s - 1960s Reports increase about side effects and dependence related to barbiturates.
- 1970 Pentobarbital (II), secobarbital (II), amobarbital (II), butabarbital (III), phenobarbital (IV), and barbital (IV) are all scheduled with the passage of the U.S. Drug Abuse Regulation and Control Act of 1970.
- 1971 Convention on Psychotropic Substances is signed in Vienna. Designed to regulate amphetamines, barbiturates, and other synthetics, the treaty today regulates amobarbital (III), butalbital (III), cyclobarbital (III), pentobarbital (III), allobarbital (IV), methylphenobarbital (IV), phenobarbital (IV), secbutabarbital (IV), and vinylbital (IV) as scheduled substances.

Poisoning

Barbiturates are sedatives used for seizure disorders, induction of anesthesia, and management of increased intracranial pressure. Barbiturates enhance the inhibitory neurotransmitter gamma amino butyric acid (GABA) and are general depressants to nerve and muscle tissue. Mild to moderate barbiturate toxicity mimics alcohol intoxication. Severe acute barbiturate toxicity results in CNS problems, including lethargy and coma. Constricted pupils, confusion, hypotension, poor coordination, respiratory depression, and coma may be found on physical exams. Although a barbiturate serum level may be obtained, the clinical presentation predicts the seriousness of the overdose. Attention must be given to the ABC's - airway, breathing and circulation. Gastric Lavage and multiple doses of activated charcoal may be used to decontaminate the GI system. IV fluids and forced diuresis and alkalinization should be used for long acting barbiturate intoxication. In severe cases, hemodialysis may be necessary. Early deaths are usually a result of shock or cardiopulmonary arrest. Later deaths are usually the result of pulmonary complications such as aspiration pneumonia or pulmonary edema.

Famous users

- Ryunosuke Akutagawa - the renowned Japanese writer who wrote Rashomon , committed suicide by overdosing on barbiturates on July 24, 1927.
 Judy Garland died from an accidental barbiturate overdose
 Marilyn Monroe also died from an overdose of barbiturates, as did George Sanders, Kenneth Williams (although an open verdict was recorded) and Jean Seberg.
 Michael Rabin, one of the most prodigious violinists America has ever had,

became dependent on barbiturates and his death was partially linked to abuse of these drugs.

Jimi Hendrix's death was a combination of barbiturate overdose and vomit inhalation.

Edie Sedgwick died in 1971 of barbiturate overdose. Death was said to be accidental/suicidal.

Tim Buckley, singer-songwriter and father of Jeff Buckley, died from an accidental overdose of heroin, alcohol, and barbiturates.

Ruan Lingyu committed suicide by overdosing on barbiturates on March 8, 1935.

Johnny Cash abused barbiturates during the height of his career.

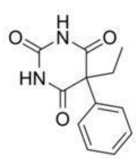
Elvis Presley used barbiturates in the last years of his life, but whether this contributed to his death is disputed.

Margaux Hemingway died from an overdose of phenobarbital.

Dorothy Kilgallen died in 1965 of an alcohol and seconal overdose. It is unclear whether the overdose was accidental or murder.

Diane Arbus committed suicide in 1971 by taking barbiturates and slitting open her wrists.

Phenobarbital



Systematic (IUPAC) name

5-ethyl-5-phenyl-1,3-diazinane-2,4,6-trione

Pharmacokinetic data

Bioavailability **>95%**

Protein binding 20 to 45%

Metabolism Hepatic (mostly CYP2C19)

Half life 53 to 118 hours

Excretion Renal and fecal

Therapeutic considerations

Pregnancy cat. $D_{(US)}$

Legal status Class B(UK) Schedule IV(US)

Routes Oral, rectal, parenteral (intramuscular and intravenous)

Phenobarbital (INN) or *phenobarbitone* (former BAN) is a barbiturate, first marketed as *Luminal*® by Farbwerke Fr. Bayer and Co. It is the most widely used anticonvulsant worldwide and the oldest still in use. It also has sedative and hypnotic properties but, as with other barbiturates, has been superseded by the benzodiazepines for these indications. The World Health Organization recommends its use as first-line for partial and generalized tonic–clonic seizures in developing countries. It is a core medicine in the WHO Model List of Essential Medicines, which is a list of minimum medical needs for a basic health care system.[1] In more affluent countries, it is no longer recommended as a first or second-line choice anticonvulsant for most seizure types,[2][3] though it is still commonly used to treat neonatal seizures.[4]

History

The first barbiturate drug, barbital, was synthesized in 1902 by German chemists Emil Fischer and Joseph von Mering at Bayer. By 1904 several related drugs, including phenobarbital, had been synthesized by Fischer. Phenobarbital was brought to market in 1912 by the drug company Bayer using the brand Luminal. It remained a commonly prescribed sedative and hypnotic until the introduction of benzodiazepines in the 1950s.[5]

Phenobarbital's soporific, sedative and hypnotic properties were well known in 1912, but nobody knew it was also an effective anticonvulsant. The young doctor Alfred Hauptmann gave it to his epilepsy patients as a tranquiliser and discovered that their epileptic attacks were susceptible to the drug. Hauptmann performed a careful study of his patients over an extended period. Most of these patients were using the only effective drug then available, bromide, which had terrible side effects and limited efficacy. On

phenobarbital, their epilepsy was much improved: the worse patients suffered fewer and lighter seizures and some patients became seizure free. In addition, they improved physically and mentally as bromides were removed from their regime. Patients who had been institutionalised due to the severity of their epilepsy were able to leave and, in some cases, resume employment. Hauptman dismissed concerns that its effectiveness in stalling epileptic attacks could lead to patients suffering a build-up that needed to be "discharged". As he expected, withdrawal of the drug lead to an increase in seizure frequency – it was not a cure. The drug was quickly adopted as the first widely effective anticonvulsant, though World War I delayed its introduction in the U.S.[6]

Phenobarbital was used to treat neonatal jaundice by increasing liver metabolism and thus lowering bilirubin levels. In the 1950s, phototherapy was discovered, and became the standard treatment.[7]

In 1940, Winthrop Chemical produced sulfathiazole tablets that were contaminated with phenobarbital. This occurred because both tablets were produced side-by-side and equipment could be interchanged. Each antibacterial tablet contained more than twice the required dose of phenobarbital necessary to induce sleep. Hundreds of patients died or were injured as a result. A U.S. Food and Drug Administration investigation was highly critical of Winthrop and the scandal lead to the introduction of Good Manufacturing Practice for drugs.[7]

Phenobarbital was used for over 25 years as prophylaxis in the treatment of febrile seizures.[8] Although an effective treatment in preventing recurrent febrile seizures, it had no positive effect on patient outcome or risk of developing epilepsy. The treatment of simple febrile seizures with anticonvulsant prophylaxis is no longer recommended.[9][10]

Indications

Phenobarbital is indicated in the treatment of all types of seizures except absence seizures.[2][11] Phenobarbital is no less effective at seizure control than more modern drugs such as phenytoin and carbamazepine. It is, however, significantly less well tolerated.[12][13]

The first line drugs for treatment of status epilepticus are fast acting benzodiazepines such as diazepam or lorazepam. If these fail then phenytoin may be used, with phenobarbital being an alterntive in the US but used only third line in the UK.[14] Failing that, the only treatment is anaesthesia in intensive care.[11][15]

Phenobarbital is the first line choice for the treatment of neonatal seizures.[4][16][17] Concerns that neonatal seizures in themselves could be harmful make most physicians treat them aggressively. There is, however, no reliable evidence to support this approach.[18]

Side effects

Sedation and hypnosis are the principal side effects of this drug. CNs effects like dizziness, nystagmus and ataxia are also common. In old aged patients, they cause excitement and confusion while in children, they cause paradoxical hyperreactivity.

Contraindications

Acute intermittent porphyria, oversensitivity for barbiturates, prior dependence on barbiturates, severe respiratory insufficiency and hyperkinesia in children.

Overdose

Poisoning by barbiturates

Classifications and external resources

ICD-10

T42.3

eMedicine

med/207

Phenobarbital causes a "depression" of the body's systems, mainly the central and peripheral nervous systems; thus, the main characteristic of phenobarbital overdose is a "slowing" of bodily functions, including decreased consciousness (even coma), bradycardia, bradypnea, hypothermia, and hypotension (in massive overdoses). Overdose may also lead to pulmonary edema and acute renal failure as a result of shock.

The electroencephalogram of a person with phenobarbital overdose may show a marked decrease in electrical activity, to the point of mimicking brain death. This is due to profound depression of the central nervous system, and is usually reversible.[19]

Treatment of phenobarbital overdose is supportive, and consists mainly in the maintenance of airway patency (through endotracheal intubation and mechanical ventilation), correction of bradycardia and hypotension (with intravenous fluids and vasopressors, if necessary) and removal of as much drug as possible from the body. Depending on how much time has elapsed since ingestion of the drug, this may be accomplished through gastric lavage (stomach pumping) or use of activated charcoal. Hemodialysis is effective in removing phenobarbital from the body, and may reduce its half-life by up to 90%.[19] There is no specific antidote for barbiturate poisoning.

Pharmacokinetics

Phenobarbital has an oral bioavailability of approximately 90%. Peak plasma concentrations are reached 8 to 12 hours after oral administration. It is one of the longest-acting barbiturates available – it remains in the body for a very long time (half-life of 2 to 7 days) and has very low protein binding (20 to 45%). Phenobarbital is metabolized by the

liver, mainly through hydroxylation and glucuronidation, and induces most isozymes of the cytochrome P450 system. It is excreted primarily by the kidneys.

Veterinary uses

Phenobarbital is one of the initial drugs of choice to treat epilepsy in dogs, and is the initial drug of choice to treat epilepsy in cats.[20]

It may also be used to treat seizures in horses when benzodiazepine treatment has failed or is contraindicated.[21]

Heaven's Gate

The Heaven's Gate cult members committed mass suicide in 1997 with phenobarbital mixed with vodka.

Benzodiazepines

The benzodiazepines(pronounced [ÌbenzYŠdajÈæzYpiÐnz], which are considered *minor tranquilizers*) are a class of drugs with sedative, hypnotic, anxiolytic, anticonvulsant, amnestic and muscle relaxant properties. Benzodiazepines are often used for short-term relief of severe, disabling anxiety or insomnia. Long-term use can be problematic due to the development of tolerance and physiological and psychological dependency. They are believed to act on the GABA receptor GABAA, the activation of which dampens higher neuronal activity. They began to be widely prescribed for stress-related ailments in the 1960s and 1970s. Their chemical structure is based upon diazepine and phenyl groups.

Pharmacology

Benzodiazepines produce their variety of effects by modulating the GABA***A*** receptor, the most prolific inhibitory receptor within the brain. The GABA***A*** receptor is made up from 5 subunits out of a possible 19, and GABA***A*** receptors made up of different combinations of subunits have different properties, different locations within the brain and importantly, different activities in regards to benzodiazepines.

In order for GABA***A*** receptors to be sensitive to the action of benzodiazepines they need to contain an ± and a ³ subunit, where the benzodiazepine binds. Once bound, the benzodiazepine locks the GABA***A*** receptor into a conformation where the neurotransmitter GABA has much higher affinity for the GABA***A*** receptor, increasing the frequency of opening of the associated Chloride ion channel and hyperpolarising the membrane. This potentiates the inhibitory effect of the available GABA leading to sedatory and anxiolytic effects. As mentioned, different benzodiazepines can have different affinities for GABA***A*** receptors made up of different collection of subunits. For instance, benzodiazepines with high activity at the ±***1*** are associated with sedation whereas those with higher affinity for GABA***A*** receptors containing ±***2*** and/or ±***3*** subunits have good anti-anxiety activity.

Members

Benzodiazepines are commonly divided into three groups: Short-acting compounds act for less than six hours and have few residual effects if taken before bedtime, but rebound insomnia may occur and they might cause wake-time anxiety. Intermediate-acting compounds have an effect for 6-10 hours, may have mild residual effects but rebound insomnia is not common. Long-acting compounds have strong sedative effects that persist. Accumulation of the compounds in the body may occur. The elimination half-life may greatly vary between individuals, especially the elderly.

The various benzodiazepines and their respective trade-names, half-lives, and primary uses are listed in the following table.

Drug Name = Common Brand Names* = Elimination Half-Life (h) [active metabolite] = Primary Effects = Approximate Equivalent Dose*****

- Alprazolam = Xanax, Xanor, Tafil, Alprox = 6-12 hours = anxiolytic = 0.5 mg
- Bromazepam = Lexotan, Lexomil, Somalium, Bromam = 10-20 hours = anxiolytic = 5-6 mg
- Chlordiazepoxide = Librium, Tropium, Risolid, Klopoxid = 5-30 hours [36-200 hours] = anxiolytic = 25 mg
- Cinolazepam = Gerodorm = 9 h = sedative = ?
- Clobazam = Frisium, Urbanol = 12-60 hours = anxiolytic, anticonvulsant = 5-20 mg
- Clonazepam = Klonopin, Klonapin, Rivotril = 18-50 hours = anxiolytic, anticonvulsant = 0.5 mg
- Clorazepate = Tranxene = [36-100 hours] = anxiolytic, anticonvulsant = 15 mg

- Diazepam = Valium, Apzepam, Stesolid, Apozepam, Hexalid, Valaxona = 20-100 hours [36-200] = anxiolytic, hypnotic, anticonvulsant, muscle relaxant = 10 mg
- Estazolam = ProSom = 10-24 h = hypnotic = 1-2 mg
- Flunitrazepam = Rohypnol, Fluscand, Flunipam, Ronal = 18-26 hours [36-200 hours] = hypnotic = 1 mg
- Flurazepam = Dalmane = [40-250 hours] = hypnotic = 15-30 mg
- Halazepam = Paxipam = [30-100 hours] = anxiolytic = 20 mg
- Ketazolam = Anxon = 2 hours = anxiolytic = 15-30 mg
- Loprazolam = Dormonoct = 6-12 hours = hypnotic = 1-2 mg
- Lorazepam = Ativan, Temesta, Lorabenz = 10-20 hours = anxiolytic = 1 mg
- Lormetazepam = Noctamid, Pronoctan = 10-12 hours = hypnotic = 1-2 mg
- Medazepam = Nobrium = 36-200 hours = anxiolytic = 10 mg
- Midazolam = Dormicum, Versed, Hypnovel = 3 hours (1.8-6 hours) = hypnotic = 5-15 mg
- Nitrazepam = Mogadon, Apodorm, Pacisyn, Dumolid = 15-38 hours = hypnotic = 10 mg
- Nordazepam = Madar, Stilny = 50-120 hours = anxiolytic = 10 mg
- Oxazepam = Serax, Serenid, Serepax, Sobril, Oxascand, Alopam, Oxabenz, Oxapax = 4-15 hours = anxiolytic = 20 mg
- Pinazepam = Domar = [40-100 hours] = sedative = 5-20 mg
- Prazepam = Centrax = [36-200 hours] = anxiolytic = 10-20 mg
- Quazepam = Doral = 25-100 hours = hypnotic = 20 mg
- Temazepam = Restoril, Normison, Euhypnos = 8-22 hours = hypnotic = 15 mg
- Tetrazepam = Mylostan = 3-26 hours = Skeletal muscle relaxant = ?
- Triazolam = Halcion, Rilamir = 2 hours = hypnotic = 0.5 mg
- DMCM = ? = ? = anxiogenic, convulsant

not used therapeutically

*Not all trade names are listed. Click on drug name to see a more conclusive list. **The duration of apparent action is usually considerably less than the half-life. With most benzodiazepines, noticeable effects usually wear off within a few hours. Nevertheless, as long as the drug is present it will exert subtle effects within the body. These effects may become apparent during continued use or may appear as withdrawal symptoms when dosage is reduced or the drug is stopped. ***Equivalent doses are based on clinical experience but may vary between individuals.[1]

Effects/Uses

Benzodiazepines are used in many situations, depending on the pharmacokinetics of each of the constituent drugs. The main use of the short-acting benzodiazepines is in insomnia, while anxiety responds better to medium- to long-acting substances that will be required all day.

Midazolam is mostly used as an intravenous injection for sedation before surgical procedures or for emergency intubation. It is commonly used in conjunction with opiates.

All benzodiazepines have the following, predictable effects, though some may be relatively stronger anxiolytics and others relatively stronger amnesics. Each effect is more likely to occur at higher doses. Selecting the right type of benzodiazepine for a particular patient and then prescribing it at the minimum effective dose will lessen the likelihood of adverse effects.

- Anxiolytic (reduce anxiety).
- Anticonvulsant (used against epileptic seizures).
- Antispasmodic (muscle relaxant).
- Sedative / hypnotic ("sleeping tablet" effect).
- Amnesic (producing anterograde amnesia).

Side effects

The side effects are predictable as they are intrinsic effects of the drug class of benzodiazepines. Knowing the relative effects of benzodiazepine types will help clinicians prescribe the most appropriate type. For example, lorazepam may not be best choice for longer term treatment in the elderly due to its stronger amnesic effects potentially aggravating forgetfulness and confusion. But then lorazepam may be a better choice for short term treatment of a younger, non-drinking patient as it is relatively less sedating.

Benzodiazepines have replaced the barbiturates because they have a lower abuse potential and relatively lower adverse reactions (chiefly, death is a relatively common result in barbiturate overdoses) and interactions. Still, drowsiness, ataxia, confusion, vertigo, impaired judgement, and a number of other effects are common.

Benzodiazepines may impair the ability to drive vehicles and to operate machinery. The impairment is worsened by consumption of alcohol, because both act as central nervous system depressants. In fact, consuming any benzodiazepine with alcohol can result in a potentially fatal overdose. The effects of long-acting benzodiazepines can also linger over to the following day.

Tolerance

Tolerance develops to many of the therapeutic effects of benzodiazepines rapidly with daily or frequent use. Generally, tolerance to the hypnotic and sedative effects occurs within days, however, tolerance to the anxiolytic effects of benzodiazepines rarely, if ever, occurs as is evidenced by a 20-year study on alprazolam (Xanax®) in the treatment of panic disorder. [2]

Dependence

Long-term benzodiazepine usage generally leads to some form of tolerance and/or dependence. It is estimated that up to 50 percent of patients prescribed diazepam for 6 months at therapeutic dosages are physically dependent. Withdrawal symptoms due to abrupt discontinuation may include:

- Insomnia

Rebound REM (or dreaming) sleep
Anxiety, possible panic attacks
Tachycardia
Hypertension
Depression, possible suicidal ideation
Tremor
Perspiration
Loss of appetite
Dysphoria

An abrupt discontinuation of benzodiazepines may result in a severe and very unpleasant withdrawal syndrome that may additionally result in:

- Convulsions

Delusions
Psychosis
Effects similar to delirium tremens

Hence, every person on long-term or high dosage of any benzodiazepine should be slowly and carefully weaned off the drug, preferably under medical supervision by a physician who is knowledgeable about the benzodiazepine withdrawal syndrome. This can usually be avoided or minimized by use of a long half-life benzodiazepine and very gradually tapering off the drug over a period of many weeks or even months.

Onset of the withdrawal syndrome from long half-life benzodiazepines might be delayed, although withdrawal from short-acting benzodiazepines often presents early.

Some of the withdrawal symptoms are identical to the symptoms for which the medication was originally prescribed. The ability to determine the difference between relapse and rebound is very important during the withdrawal phase.

Abuse Potential

Although benzodiazepines are invaluable in the treatment of anxiety disorders, they have some potential for abuse and may cause dependence or addiction. It is important to distinguish between addiction to and normal physical dependence on benzodiazepines. Intentional abusers of benzodiazepines usually have other substance abuse problems. Benzodiazepines are usually a secondary drug of abuse, used mainly to augment the high received from another drug or to offset the adverse effects of other drugs. Few cases of addiction arise from legitimate use of benzodiazepines. [3]

Intoxication

Overdosage of benzodiazepines, particularly when combined with alcohol, may lead to coma, but does not cause severe biochemical disturbances and therefore carries a relatively

good prognosis if quantities of the substances ingested are not sufficent to cause death. The antidote for all benzodiazepines is flumazenil (Annexate®), a benzodiazepine antagonist, which is occasionally used empirically in patients presenting with unexplained loss of consciousness in an emergency room setting.

Legal status

Nearly all medically-used benzodiazepines are Schedule IV in the USA under the Federal Controlled Substances Act. In Canada benzodiazepines are also Schedule IV.

Flunitrazepam (Rohypnol) is treated more severely under Federal law than other benzodiazepines. For example, despite being Schedule IV like any other benzodiazepine, it is not commercially available in the United States. It also carries tougher Federal penalties for trafficking and possession than other Schedule IV drugs. With the exception of cases involving 5 grams or more of crack, flunitrazepam is the only controlled substance in which first-offense simple possession is a federal felony. Various other countries limit the availability of benzodiazepines legally. Even though it is a commonly prescribed class of drugs, the Medicare Prescription Drug, Improvement, and Modernization Act specifically states that insurance companies that provide Medicare Part D plans are not required to cover benzodiazepines

History

The first benzodiazepine, chlordiazepoxide (Librium®) was discovered serendipitously in 1954 by the Austrian scientist Dr Leo Sternbach (1908-2005), working for the pharmaceutical company Hoffmann-La Roche. Initially, he discontinued his work on the compound Ro-5-0690, but he "rediscovered" it in 1957 when an assistant was cleaning up the laboratory. Although initially discouraged by his employer, Sternbach conducted further research that revealed the compound was a very effective tranquilizer.

In 1963 approval for use was given to diazepam (Valium®) - a simplified version of Librium - primarily to counteract anxiety symptoms. Sleep-related problems were treated with nitrazepam (Mogadon®), which was introduced in 1965 and flurazepam (Dalmane®), which was introduced in 1973.

Routes Oral

Alprazolam is a short-acting drug in the benzodiazepine class used to treat anxiety disorders and as an adjunctive treatment for depression.

Alprazolam was invented by Pfizer and is marketed under the trade name *Xanax*. Its patent expired in September 1993.

History

Alprazolam was originally marketed as an atypical benzodiazepine, but only classified as anxiety neurosis. Researchers later speculated, however, that alprazolam could be studied for serotonergic effects. On October 20, 1976, Dr. Guy Chouinard was the first to conduct a clinical trial of alprazolam in panic disorder. Patients diagnosed with panic disorder were included among participants in the study. 50 patients were given either the alprazolam or a placebo during an 8-week double-blind controlled study. Results proved that both somatic and psychic anxiety was decreased significantly in those who took the alprazolam, compared to the placebo.

Pharmacology

Alprazolam is a triazolobenzodiazepine, that is, a benzodiazepine with a triazolo-ring attached to its structure. Alprazolam binds to the GABAA subtype of the GABA receptor, increasing inhibitory effects of GABA within the central nervous system. The binding site for benzodiazepines is distinct from the binding site for barbiturates and GABA on the GABA receptor.

Unlike other benzodiazepines, alprazolam may also have some antidepressant activity, although clinical evidence of this is lacking.

Pharmacokinetics

The mechanism of action is not fully understood. Alprazolam is readily absorbed from the gastrointestinal tract. The peak plasma concentration is achieved in 1-2 hours. Most of the drug is bound to plasma protein, mainly albumin. Alprazolam is hydroxylated in the liver to ±-hydroxyalprazolam, which is also pharmacologically active. This and other metabolites are later excreted in urine as glucuronides. Some of the drug is also excreted in unchanged form.

Indications

The main medical uses for alprazolam include:

- Treatment of panic disorder, with or without agoraphobia. Alprazolam is very effective in preventing panic attacks. However, despite its efficacy, many psychiatrists are reluctant to use alprazolam for this condition because of the possibility of dependence and interdose ("breakthrough") anxiety due to its short-acting nature. An extended-release formulation of alprazolam known as Xanax XR® was introduced in 2001 and is often preferred.
- Treatment of panic attacks. Alprazolam is taken as needed (PRN); 4 to 6 doses per day are the acceptable limit. If dependence seems to develop and/or the limit is exceeded, therapy may be reconsidered and/or discontinued.

- Long-term treatment of severe anxiety disorders. Alprazolam may be used for long-term treatment of anxiety if other therapies either do not work or are contraindicated. Duration of therapy in this case is often four months or longer. The decision to use alprazolam for this purpose must be carefully made by a specialized psychiatrist, taking into account the individual's suffering, quality of life, loss of social performance and risk of dependence.
- Adjunctive treatment of depression. SSRIs (e.g.
- Other uses. Alprazolam may be used by specialists to treat severe cases of Borderline Personality Disorder. Some studies have shown positive results.

Availability

Alprazolam is generally sold in generic form in Italy and the United States. It is also sold under many other brand names, depending on the country:

- *Aceprax*® - Uruguay
- *Alplax*® - Argentina
- *Alpralid*® - Israel
- *Alprax*® - India
- *Alviz*® - Indonesia
- *Alzolam*® - India, Malaysia
- *Apo-Alpraz*® - Canada (also made by other companies under different names)
- *Apraz*® - Brazil
- *Calmax*® - Ireland
- *Constan*® - Japan
- *Frontal XR*® - (an extended release formulation) Brazil
- *Frontal*® - Brazil
- *Frontin*® - Hungary, Slovak Republic, Czech Republic
- *Helex*® - Croatia, Slovenia
- *Kalma*® - Australia
- *Kinax*® (o‰ç) - Taiwan
- *Ksalol*® - Serbia
- *Manorest*® - Sri Lanka
- *Misar*® - Croatia
- *Neurol*® - Czech Republic, Slovak Republic
- *Niravam*® - (formulation that dissolves on the tongue) United States
- *Paxal*® - Iceland
- *Prazolex*® - Romania
- *Ralozam*® - Australia
- *Restyl*® - Bahrain, Cyprus, Egypt, India, Iran, Iraq, Jordan, Kuwait, Lebanon, Libya, Oman, Qatar, Republic of Yemen, Saudi Arabia, Syria, United Arab Emirates

- *Sedipral®* - Paraguay
- *Solanax®* - Japan
- *Tafil AP®* - (an extended release formulation) Mexico
- *Tafil®* - Costa Rica, Denmark, El Salvador, Germany, Guatemala, Honduras, Mexico, Nicaragua, Panama, Venezuela
- Trankimazin® - *Spain*
- *Tranquinal®* - Ecuador, Peru
- *Xanax XR®* - (an extended release formulation) Israel [1], United States, Portugal
- *Xanax®* - Australia, Belgium, Croatia, Germany, Greece, Hungary, Ireland, Italy, Netherlands, New Zealand, Pakistan, Portugal, Switzerland, Turkey, United Kingdom, United States
- *Xanor®* - Austria, Finland, Norway, Philippines, South Africa, Sweden
- *Zamhexal®* - Australia
- *Zolarem®* - Bahrain, Benin, Burkina-Faso, Cyprus, Egypt, Ethiopia, Gambia, Ghana, Guinea, Iran, Iraq, Israel, Ivory Coast, Jordan, Kenya, Kuwait, Lebanon, Liberia, Libya, Malawi, Mali, Mauritania, Mauritius, Morocco, Niger, Nigeria, Oman, Qatar, Republic of Yemen, Saudi Arabia, Senegal, Seychelles, Sierra-Leone, South Africa, Sudan, Syria, Tanzania, Tunia, Uganda, United Arab Emirates, Zambia, Zimbabwe
- *Zoldac®* - Benin, Burkina-Faso, Ethiopia, Gambia, Ghana, Guinea, India, Ivory Coast, Kenya, Liberia, Malawi, Mali, Mauritania, Mauritius, Morocco, Niger, Nigeria, Senegal, Seychelles, Sierra-Leone, South Africa, Sudan, Tanzania, Tunia, Uganda, Zambia, Zimbabwe

Packaging

Appearance is generally as follows in the United States.

Alprazolam

Inscriptions on tablet vary depending on manufacturer.
.25 mg White oval tablet scored
.5 mg Peach oval tablet scored (.5 mg and .25 mg Alprazolam may also be found in White round tablet scored)
1 mg Blue oval scored tablet. May also be called a "football."
2 mg White rectangle multi-scored tablet. May also be called a "bar" or "stick."

Xanax XR

.5 mg White pentagonal tablet Imprinted "X /0.5"
1 mg Yellow square tablet Imprinted "X / 1"
2 mg Blue round tablet Imprinted "X / 2"
3 mg Green triangular tablet Imprinted "X / 3"

Side effects

Common side effects of alprazolam can include:

- Somnolence (drowsiness)
- Euphoria
- Confusion

Less common side effects can include:

- Fatigue
- Headache

Rare side effects can include:

- Sleep apnea

Hypoventilation (Respiratory depression)
Blurred vision
Difficulty in depth perception
Slurred speech or dysarthria
Changes in personality
Confusion
Disorientation
Amnesia (memory impairment)
Vivid dreams and/or nightmares
Jaundice
Tachycardia
Bradycardia
Changes in plasma cortisol and ACTH levels
Blood dyscrasias
Decreased salivation
Increased salivation
Diarrhea
Constipation
Nausea
Elevated hepatic (liver) enzymes
Incontinence

Rare paradoxical side effects can include:

- Nervousness
- Anxiety
- Agitation
- Rage
- Insomnia
- Muscle spasms and rigidity

Paradoxical side effects are usually a result of too high a dose (sometimes deliberate) and/or combination with alcohol. Adjusting the dosage usually causes them to cease.

Concentrations of alprazolam in cigarette smokers may be reduced up to 50% when compared to non-smokers.[3].

Long-term treatment with alprazolam may lead to physical and/or psychological dependence. Users often develop a tolerance to the drug's sedative effects, though tolerance to its anxiolytic efficacy rarely develops when used at theraputic dosage levels.

There is now a general consensus among many psychiatrists that alprazolam (a so-called 'high-potency' benzodiazepine) poses a particularly high risk for misuse, abuse and dependence. Withdrawal after long-term treatment should be done slowly over a period of weeks (or even months) to avoid serious withdrawal symptoms such as agitation, panic attacks, rebound anxiety, muscle cramps and seizures. Some patients may benefit from a substitution with diazepam or clonazepam as these drugs remain in the bloodstream longer and have a somewhat lower risk of dependency.

Patients taking a dosing regimen larger than 4mg per day have an increased potential for emotional and physical dependence. Patients who have this dependence may find it difficult to discontinue use and should seek a healthcare professional immediately so they may put you on a proper regimen to discontinue use. In addition to dependence, this medication may cause withdrawal symptoms, and in some cases has been known to cause seizures. The use of this medication may also cause a reaction called rebound anxiety. When a patient discontinues use, they may experience the symptoms they had before taking medication, but this is usually short lived. Symptoms may also be accompanied other reactions including changes in mood, anxiety or sleep. Rebound anxiety is usually a result of abrupt discontinuation of this medication; patients who taper off are less likely to experience these symptoms.

Contraindications

Use of alprazolam should be avoided in individuals with the following conditions:

- Myasthenia gravis

Acute intoxication with alcohol, narcotics, or other psychoactive substances
Ataxia
Severe hypoventilation
Acute narrow-angle glaucoma
Severe liver deficiencies (e.g. hepatitis and cirrhosis)
Severe sleep apnea
Hypersensitivity or allergy to any drug in the benzodiazepine class

Women who are pregnant should avoid alprazolam. Children of mothers who are taking alprazolam are considered at risk for withdrawal symptoms during the postnatal period. Some children born under these conditions have been reported to have neonatal flaccidity and respiratory problems. Likewise, nursing mothers should avoid alprazolam due to the fact that Benzodiazepines are known to be passed into breast milk. This can cause infants to become lethargic and loose weight. [4] [5]

Elderly individuals should be cautious in the use of alprazolam due to the possibility of increased sensitivity to side effects, especially loss of coordination and drowsiness. [6]

Eating grapefruits or drinking grapefruit juice should be avoided by those taking alprazolam.

Patients at a High Risk for Abuse and Dependence

At a particularly high risk for misuse, abuse, and dependence are:

- Patients with a history of alcohol or drug abuse and/or dependence
- Emotionally unstable patients
- Patients with severe personality disorders
- Patients with chronic pain or other physical disorders

Patients from the aforementioned group should be monitored very closely during therapy for signs of abuse and development of dependence. Discontinue therapy if any of these signs are noted. Long-term therapy in these patients is not recommended.

Recreational use

Alprazolam, like all benzodiazepines, has the potential for abuse, especially in individuals prone to addiction. Although it is not manufactured illegally, it is often diverted to the black market. The state of relaxation, anxiolysis, disinhibition and euphoria induced by benzodiazepines is the main reason for their illicit use.

Injecting alprazolam is highly dangerous. When crushed in water, it will not dissolve, potentially causing severe damage to arteries. While it is somewhat soluble in alcohol, the combination of the two, particularly when injected, can easily cause a serious (and potentially fatal) overdose. Alprazolam may also be insufflated.

Alprazolam is sometimes used with other recreational drugs to relieve the panic or distress of dysphoric reactions to psychedelics such as LSD and also to promote sleep in the "come-down" period following use of recreational drugs with stimulant or insomniac properties (such as LSD, cocaine, Amphetamine, DXM, and MDMA). It is also often used in conjunction with marijuana or heroin to potentiate the relaxing effect. It is also sometimes used by heroin addicts to suppress withdrawal symptoms.

Legal status

In the United States, alprazolam is a prescription drug and is assigned to Schedule IV of the Controlled Substances Act by the Drug Enforcement Administration. Internationally, alprazolam is included under the United Nations Convention on Psychotropic Substances.

Routes Oral, IM, IV, suppository

Diazepam (IPA: [dajÈæzjpæm]), marketed under brand names *Valium*, *Stesolid*, *Seduxen*, *Bosaurin*, *Diapam*, *Antenex* and *Apozepam*)[1] is a drug which is a benzodiazepine derivative. It possesses anxiolytic, anticonvulsant, sedative, skeletal muscle relaxant and amnestic properties. This makes it a useful drug for treating anxiety, insomnia, seizures, alcohol withdrawal, and muscle spasms. It is also used before certain medical procedures (such as endoscopies) to reduce tension and anxiety, and in some surgical procedures to induce amnesia.[2][3]

Diazepam is a core medicine in the World Health Organization's "Essential Drugs List", which is a list of minimum medical needs for a basic health care system.[4] Diazepam is used to treat a wide range of conditions and is one of the most frequently prescribed benzodiazepines.

Benzodiazepine

Diazepam is a benzodiazepine that binds to a specific subunit on the GABA*A* receptor at a site that is distinct from the endogenous GABA molecule.[5][6]The GABA*A* receptor is an inhibitory channel which, when activated, decreases neurologic activity.

Due to the role of diazepam as a positive allosteric modulator of GABA, when it binds to benzodiazepine receptors it causes inhibitory effects. This arises from the hyperpolarization of the postsynaptic membrane, due to the control exerted over negative chloride ions by GABA*A* receptors.[5][7]

Diazepam appears to act on areas of the limbic system, thalamus and hypothalamus, inducing anxiolytic effects. Its actions are due to the enhancement of GABA activity.[2][5]

History

Diazepam was the second benzodiazepine to be invented by Leo Sternbach of Hoffmann-La Roche, and was approved for use in 1963. It is five times more potent than its predecessor, chlordiazepoxide, which it quickly surpassed in terms of sales. After this initial success, other pharmaceutical companies began to introduce other benzodiazepine derivatives.[8]

The benzodiazepines gained popularity among medical professionals as an improvement upon barbiturates, which have a comparatively narrow therapeutic index, and are far more sedating at therapeutic doses. The benzodiazepines are also far less dangerous; death rarely results from diazepam overdose, except in cases where it is consumed with large amounts of other depressants (such as alcohol or other sedatives).[9]

Diazepam was the top-selling pharmaceutical in the United States from 1969 to 1982, with peak sales in 1978 of 2.3 billion pills.[8] In 1966, The Rolling Stones released the song "Mother's Little Helper", which is about a mother needing the "little yellow pill" to get through the day.[10]

Over the years, physicians, psychiatrists and neurologists have discovered many new off-label uses for diazepam, such as treatment of spastic paresis and palliative treatment of stiff-person syndrome.[11] Diazepam is also found in nature. Several plants, such as potato and wheat, contain trace amounts of naturally occurring diazepam and other benzodiazepines.[12]

Pharmacokinetics

Diazepam can be administered orally, intravenously, intramuscularly, or as a suppository..[13]

When diazepam is administered orally, it is rapidly absorbed and has a fast onset of action. The onset of action is 1-5 minutes for IV administration and 15-30 minutes for IM administration. The duration of the diazepam's main pharmacological effects is 15 minutes to 1 hour for both routes of administration.[14]

Peak plasma levels are achieved 30 minutes to 2 hours after oral administration. When diazepam is administered as an intramuscular injection, absorption is slow, erratic and incomplete.[1][15]

Diazepam is highly lipid-soluble, and is widely distributed throughout the body after administration. It easily crosses both the blood-brain barrier and the placenta, and is excreted into breast milk. After absorption, diazepam is redistributed into muscle and

adipose tissue. Continual daily doses of diazepam will quickly build up to a high concentration in the body (mainly in adipose tissue), which will be far in excess of the actual dose for any given day.[13][15]

Diazepam is metabolised in the liver via the cytochrome P450 enzyme system. It has a biphasic half-life of 1-2 and 2-5 days, and has several pharmacologically active metabolites. The main active metabolite of diazepam is desmethyldiazepam (also known as nordazepam or nordiazepam). Diazepam's other active metabolites include temazepam and oxazepam. These metabolites are conjugated with glucuronide, and are excreted primarily in the urine. Because of these active metabolites, the serum values of diazepam alone are not useful in predicting the effects of the drug.[1][15]

Diazepam has a half-life (t1/2±) of 20-50 hours, and desmethyldiazepam has a half-life of 30-200 hours.[15]

Most of the drug is metabolised; very little diazepam is excreted unchanged.[13]

In humans, the protein binding of diazepam is around 98.5%.[1]

Indications

Diazepam is mainly used to treat anxiety, insomnia, and symptoms of acute alcohol or opiate withdrawal. It is also used as a premedication for inducing sedation, anxiolysis or amnesia prior to certain medical procedures (e.g. endoscopy).[1]

Diazepam is rarely used as a primary drug for the long-term treatment of epilepsy. This is due to the fact that tolerance to the anticonvulsant effects of diazepam usually develops within 6 to 12 months of treatment, effectively rendering it useless for this purpose.[13]

Diazepam has a broad spectrum of indications (most of which are off-label), including:

- Treatment of anxiety, panic attacks, and states of agitation[1]
- Treatment of status epilepticus, adjunctive treatment of other forms of epilepsy[1]
- Treatment of the symptoms of alcohol and opiate withdrawal[1]
- Short-term treatment of insomnia[1]
- Treatment of tetanus, together with other measures of intensive-treatment[16]
- Initial management of mania, together with firstline drugs like lithium, valproate or other antipsychotics
- Adjunctive treatment (with antidepressants) of depression with symptoms of anxiety
- Adjunctive treatment (with antipsychotics), in patients who develop early extrapyramidal side-effects
- Adjunctive treatment of painful muscle conditions[11]
- Adjunctive treatment of spastic muscular paresis (para-/tetraplegia) caused by cerebral or spinal cord conditions such as stroke, multiple sclerosis, spinal cord injury (long-term treatment is coupled with other rehabilitative measures)[11]
- Palliative treatment of stiff person syndrome[7]
- Pre-/postoperative sedation, anxiolysis and/or amnesia (e.g. before endoscopic or surgical procedures)[11]
- Treatment of overdosage with hallucinogens or CNS stimulants[13]
- Adjunctive treatment of drug-induced seizures, resulting from exposure to sarin,

VX, soman (or other organophosphate poisons; See CANA), lindane, chloroquine, physostigmine, or pyrethroids[13]
Emergency treatment of eclampsia, along with IV magnesium sulfate
Prophylactic treatment of oxygen toxicity during hyperbaric oxygen therapy.[17]
Used in the treatment for irritable bowel syndrome. [18]

Veterinary uses

Diazepam is used as a short term sedative and anxiolytic for cats and dogs. It is also used for short-term treatment of seizures in dogs and short-term and long-term treatment of seizures in cats. For emergent treatment of seizures, the typical dose is 0.5 mg/kg intravenously or 1-2 mg/kg per rectum of the injectable solution.[19]

Dosage

Dosages should be determined on an individual basis, depending upon the condition to be treated, the severity of symptoms, the body weight of the patient, and any comorbid conditions the patient may have.[13]

Elderly patients and those with liver disorders experience decreased metabolism of diazepam; therefore the dosage for these patients should be reduced. General guidelines for this group of patients: initial doses of 2mg to 2.5mg, 1 or 2 times daily; increase gradually as required/tolerated.[7]

Adult dosage recommendations

- Insomnia - Up to 30mg orally, as a single dose, at bedtime.[13]
- Anxiety/panic attacks - Dosage differs depending upon severity of symptoms. For panic attacks, diazepam is taken "as needed".
    - Oral - 2mg to 10mg oral, 2 to 4 times daily.[7]
    - IV/IM - 2mg to 10mg. Repeat in 3 to 4 hours, if necessary.[11]
- Pre-/postoperative sedation - If other premedications are used, they must be administered separately.[11]
    - Oral - Up to 20mg as a single dose.[13]
    - IV/IM - 2mg to 10mg, repeated at intervals of at least 5 to 10 minutes, until adequate sedation and/or anxiolysis is achieved.[13]
- Status epilepticus
    - Oral - 2mg to 10mg, 2 to 4 times daily.[7]
    - IV/IM - 5mg to 10mg. May be repeated every 5 to 10 minutes until termination of seizures. Maximum dose of 40mg to 60mg can be used; if this dose is ineffective, other anticonvulsant drug therapy should be instituted.[13]

  - Rectal solution - 10mg as a single dose. May be repeated after 5 minutes, if necessary. The oral solution can also be administered rectally.[13]
- Painful muscle conditions or muscle spasms
  - Oral - Up to 15mg daily, in divided doses. In severe spasticity associated with cerebral palsy, doses may be increased gradually up to 60mg daily.[13]
  - IV/IM - 5mg to 10mg initially, then 5mg to 10mg in 3 to 4 hours, if necessary.[11]
- Tetanus - 100 to 300µg/kg intravenously, repeated every 1 to 4 hours.[13]
- Spastic paresis - Usually starting with 3 times daily 2mg, increasing to up to 3 times 20mg in slow increments, taking care to avoid ataxia.
- Alcohol/opioid withdrawal - For symptomatic relief of agitation, tremor, delirium tremens and hallucinosis.
  - Oral - 10mg, 3 or 4 times during the first 24 hours. Reduce to 5mg, 3 or 4 times a day, or as needed.[7]
  - IV/IM - 10mg initially, 5mg to 10mg in 3 to 4 hours, if necessary.[11]
- Initial treatment of mania - 30 to 40mg daily oral or rectal, rarely more.
- Overdosage with hallucinogens/CNS stimulants - Normally a single intravenous dose of 10 to 20mg is sufficient.
- Adjunctive treatment of depression - Usually 10 to 30mg daily oral, the greater part of the dose given at bedtime. The doses should be decreased and the medication stopped as soon as the clinical situation allows.
- Adjunctive treatment of extrapyramidal side-effects - Depends on the individual. Effective dose(s) unknown. Do not administer for more than 4 weeks.[20]
- Cardioversion - To relieve anxiety/tension and to reduce recall of procedure. 5mg to 15mg IV, 5 to 10 minutes prior to the procedure.[11]
- Prophylactic treatment of oxygen toxicity during hyperbaric therapy - 5mg to 10mg.[17]

Pediatric dosage recommendations

- Patients over 6 months of age:
  - Initiate therapy with the lowest effective dose.[7]
  - Oral: Initial dose of 40 to 200µg/kg of bodyweight. Can be repeated as tolerated, up to 4 times daily.[13]
  - Rectal suppository: 40 to 200µg/kg of bodyweight, which can be repeated as tolerated up to 4 times daily.[13]
    - Sedation or muscle relaxation[13]
      - IV/IM - 200µg/kg of bodyweight.
    - Status epilepticus[13]
      - IV/IM - 200 to 300µg/kg of bodyweight. May be repeated after 5 to 10 minutes, if required.

- Rectal solution - 5mg (for patients 1 to 3 years of age); repeat after 5 to 10 minutes, if necessary.
- Tetanus[11]
  - Patients 30 days to 5 years of age - 1mg to 2mg IV/IM, slowly; repeat every 3 to 4 hours, as necessary.
  - Patients 5 years of age or older - 5mg to 10mg IV/IM, slowly; repeat every 3 to 4 hours, as necessary.
- Convulsive disorders[11]
  - Patients 30 days to 5 years of age - 0.2mg to 0.5mg IV/IM, slowly, every 2 to 5 minutes. Maximum dose of 5mg.
  - Patients 5 years of age or older - 1mg IV/IM, slowly, every 2 to 5 minutes. Maximum of dose of 10mg. Repeat in 2 to 4 hours, if necessary.

- Patients under 6 months of age:
  - Diazepam should not be given to children under 6 months of age.[7]

Availability

Diazepam is supplied in the following forms:

- For oral administration:
  - Tablets - 2mg, 5mg, 10mg[7]. Generic versions available.
  - Capsules, time-release - 15mg (marketed by Roche as *Valrelease*®)[15]
  - Liquid solution - 1mg/ml in 500ml containers and unit-dose (5mg & 10mg); 5mg/ml in 30 ml dropper bottle (marketed by Roxane as *Diazepam Intensol*®)[15]
- For parenteral administration:
  - Solution for IV/IM injection - 5mg/ml. 2ml ampoules and syringes; 1ml, 2ml, 10ml vials; 2 ml Tel-E-Ject; also contains 40% propylene glycol, 10% ethyl alcohol, 5% sodium benzoate and benzoic acid as buffers, and 1.5% benzyl alcohol as a preservative.[21][15]
- For rectal administration:
  - Solution[13]
  - Suppositories - 5mg and 10mg[22][13]
- For inhalation administration:This method uses heating diazepam to form a vapor later producing an aerosol. This allows the drug to be passed through an inhalation route during an inhalation therapy.Provided in doses 2mg-20mg either in a single inhalation or multiple small inhalations [23]

Side effects

Diazepam has a range of side effects which are common to most benzodiazepines. Most common side effects include:

- Somnolence

- Suppression of REM sleep or dreaming
- Impaired motor function
    - Impaired coordination
    - Impaired balance
    - Dizziness
- Depression

Anterograde amnesia (especially pronounced in higher doses) Reflex tachycardia[14]

Rare paradoxical side effects can include: nervousness, irritability, insomnia, muscle cramps, and in extreme cases, rage, and violence.[24][25][26] If these side effects are present, diazepam treatment should be immediately terminated.

Up to 30% of individuals treated on a long-term basis develop a form of dependence known as "low-dose-dependence". These patients do not develop a tolerance, and do not need increasingly large doses to experience the euphoric side effects of the drug.

Diazepam may impair the ability to drive vehicles or operate machinery. The impairment is worsened by consumption of alcohol, because both act as central nervous system depressants.[7]

During the course of therapy, tolerance to the sedative effects usually develops, but not to the anxiolytic and myorelaxant effects.[27]

Patients with severe attacks of apnea during sleep may suffer respiratory depression (hypoventilation) leading to respiratory arrest and death.

Organic changes such as leukopenia[28] and liver-damage of the cholostatic type with or without jaundice (icterus) have been observed in a few cases.

Interactions

If diazepam is to be administered concomitantly with other drugs, attention should be paid to the possible pharmacological interactions. Particular care should be taken with drugs that enhance the effects of diazepam, such as barbiturates, phenothiazines, narcotics and antidepressants.[7]

Diazepam does not increase or decrease hepatic enzyme activity, and does not alter the metabolism of other compounds. There is no evidence which would suggest that diazepam alters its own metabolism with chronic administration.[13]

Agents which have an effect on hepatic cytochrome P450 pathways or conjugation can alter the rate of diazepam metabolism. These interactions would be expected to be most significant with long-term diazepam therapy, and their clinical significance is variable.[13]

- Diazepam increases the central depressive effects of alcohol, other hypnotics/sedatives (e.g. barbiturates), narcotics, and other muscle relaxants. The euphoriant effects of opioids may be increased, leading to increased risk of psychological dependence.[29][30]
  Cimetidine, omeprazole, ketoconazole, itraconazole, disulfiram, fluvoxamine, isoniazid, erythromycin, probenecid, propranolol, imipramine, ciprofloxacin, fluoxetine and valproic acid prolong the action of diazepam by inhibiting its elimination.[13][15]

Oral contraceptives ("the pill") significantly decrease the elimination of desmethyldiazepam, a major metabolite of diazepam.[30]
Rifampin, phenytoin, carbamazepine and phenobarbital increase the metabolism of diazepam, thus decreasing drug levels and effects.[13]
Nefazodone can cause increased blood levels of benzodiazepines.[30]
Cisapride may enhance the absorption, and therefore the sedative activity, of diazepam.[31]
Small doses of theophylline may inhibit the action of diazepam.[32]
Diazepam may block the action of levodopa (used in the treatment of Parkinson's Disease).[29]
Diazepam may alter digoxin serum concentrations.[13]
Other drugs that may have interactions with diazepam include: Antipsychotics (e.g. chlorpromazine), MAO inhibitors, ranitidine.[30]
Smoking tobacco can enhance the elimination of diazepam and decrease its action.[29]
Foods that acidify the urine can lead to faster absorption and elimination of diazepam, reducing drug levels and activity.[29]
Foods that alkalinize the urine can lead to slower absorption and elimination of diazepam, increasing drug levels and activity.[13]
There are conflicting reports as to whether food in general has any effects on the absorption and activity of orally administered diazepam.[29]

Contraindications

Use of diazepam should be avoided, when possible, in individuals with the following conditions:

- Ataxia

Severe hypoventilation
Acute narrow-angle glaucoma
Severe hepatic deficiencies (hepatitis and liver cirrhosis decrease elimination by a factor of 2)
Severe renal deficiencies (e.g. patients on dialysis)
Severe sleep apnea
Severe depression, particularly when accompanied by suicidal tendencies
Acute intoxication with alcohol, narcotics, or other psychoactive substances
Myasthenia gravis
Hypersensitivity or allergy to any drug in the benzodiazepine class

Special caution needed

- Pediatric patients
    - Less than 18 years of age - Treatment usually not indicated, except treatment of epilepsy, and pre-/postoperative treatment. The smallest possible effective dose should be used for this group of patients.[30]

  - Under 6 months of age - Safety and effectiveness have not been established; diazepam should not be given to individuals in this age group.[7][30]
- Elderly and very ill patients - Possibility that apnea and/or cardiac arrest may occur. Concomitant use of other central nervous system depressants increases this risk. The smallest possible effective dose should be used for this group of patients..[7][30][33]
- I.V. or I.M. injections in hypotensive individuals or those in shock should be administered carefully and vital signs should be monitored.[33]

Patients at a high risk for abuse and dependence

Diazepam can lead to physiological tolerance, and psychological and/or physical dependence. At a particularly high risk for diazepam misuse, abuse, and dependence are:

- Patients with a history of alcohol or drug abuse or dependence[7][34]
- Emotionally unstable patients
- Patients with severe personality disorders, such as Borderline Personality Disorder[35]
- Patients with chronic pain or other physical disorders

Patients from the aforementioned groups should be monitored very closely during therapy for signs of abuse and development of dependence. Discontinue therapy if any of these signs are noted. Long-term therapy in these patients is not recommended.[7][34] The American Society of Addiction Medicine has policy indicating that patients with addictive disease should not be presecribed benzodiazepines such as diazepam.

Withdrawal

Administration of therapeutic doses of diazepam for 6 weeks or longer can result in physical dependence, characterized by a withdrawal syndrome when the drug is discontinued. With larger doses, physical dependence develops more rapidly.[13]

After continued therapy in excess of a few weeks, diazepam should never be stopped abruptly. The dose should instead be lowered gradually, over a period of 2 to 4 weeks, in order to minimize withdrawal symptoms.[13][34]

Withdrawal symptoms are initially minimal, and increase in severity over the first 5 to 9 days after ingestion of the drug is stopped. Diazepam's long half-life and active metabolites delay the onset of such symptoms.[13]

The withdrawal symptoms for diazepam are similar to those of other CNS depressants (e.g. alcohol, barbiturates), and can include[13]:

- Anxiety
- Dysphoria
- Irritability
- Insomnia
- REM Rebound

- Confusion
- Tremors
- Muscle spasms
- Abdominal and muscle cramps
- Anorexia (i.e. lack of appetite)
- Nausea/vomiting
- Hyperthermia/sweating
- Hypotension

In severe cases of diazepam withdrawal, symptoms can include:

- Convulsions (i.e. seizures)
- Death

The more severe side effects usually only develop for patients who were treated with excessive doses for extended periods of time. Usually only the milder symptoms develop in patients terminating therapeutic-level treatment after several months.[7]

Overdose

An individual who has consumed too much diazepam will display one or more of the following symptoms[7][36]:

- Somnolence/difficulty staying awake
- Mental confusion
- Hypotension
- Impaired motor functions
  - Impaired reflexes
  - Impaired coordination
  - Impaired balance
  - Dizziness
- Coma

Although not usually fatal when taken alone, a diazepam overdose is considered a medical emergency and generally requires the immediate attention of medical personnel. The antidote for an overdose of diazepam (or any other benzodiazepine) is flumazenil (Anexate®). This drug is only used in cases with severe respiratory depression or cardiovascular complications. Because flumazenil is a short-acting drug and the effects of diazepam can last for days, several doses of flumazenil may be necessary. Artificial respiration and stabilization of cardiovascular functions may also be necessary. Although not routinely indicated, activated charcoal can be used for decontamination of the stomach following a diazepam overdose. Emesis is contraindicated. Dialysis is minimally effective. Hypotension may be treated with levarterenol or metaraminol.[13][9][7][36]

The oral LD***50*** (lethal dose in 50% of the population) of diazepam is 720mg/kg in mice and 1240mg/kg in rats.[7] D. J. Greenblatt and colleagues reported in 1978 on two patients who had taken 2000 and 500 mg of diazepam, respectively, went into moderately deep comas, and were discharged within 48 hours without having experienced important complications in spite of having high concentrations of diazepam and its metabolites—

desmethyldiazepam, oxazepam, and temazepam—according to samples taken in the hospital and as follow-up.[37]

Overdoses of diazepam with alcohol and/or other depressants may be fatal.[9]

Recreational use

Generally, diazepam is not used as a recreational drug as frequently as alprazolam or flunitrazepam.

Diazepam is often found as an adulterant in heroin.[38] This may be because diazepam greatly amplifies the effects of opioids.

Sometimes diazepam is used by stimulant abusers to 'come down' and sleep and to help control the urge to binge[39] and also by users of LSD and other hallucinogens to help ease their trip without unpleasant after-effects.

Legal status

Internationally, diazepam is a Schedule IV drug under the Convention on Psychotropic Substances.[40]

Physical properties

Diazepam occurs as solid white or yellow crystals and has a melting point of 131.5 to 134.5°C. It is odorless, and has a slightly bitter taste. The British Pharmacopoeia lists diazepam as being very slightly soluble in water, soluble in alcohol and freely soluble in chloroform. The United States Pharmacopoeia lists diazepam as soluble 1 in 16 of ethyl alcohol, 1 in 2 of chloroform, 1 in 39 of ether, and practically insoluble in water. The pH of diazepam is neutral (i.e. 7). Diazepam has a shelf-life of 5 years for oral tablets and 3 years for IV/IM solution.[13]

Diazepam should be stored at room temperature (15°-30°C). The solution for parenteral injection should be protected from light and kept from freezing. The oral forms should be stored in air-tight containers and protected from light.[15]

Diazepam can absorb into plastic, and therefore diazepam solution is not stored in plastic bottles or syringes. It can absorb into plastic bags and tubing used for intervenous infusions. Absorption appears to be dependent on several factors such as temperature, concentration, flow rates and tube length. Diazepam should not be administered if a precipitate has formed and will not dissolve.[15]

Formula C16H12FN3O3

Mol. weight 313.3

Pharmacokinetic data

Metabolism Hepatic

Half life 18-26 hours

Excretion Renal

Therapeutic considerations

Legal status Schedule III(US)

Routes Oral

Flunitrazepam (formerly marketed under the trade name *Rohypnol* in North America, pronounced ÌfluĐnajÈtræzYpæm) is a drug which is a benzodiazepine derivative. It has powerful sedative, anxiolytic, and skeletal muscle relaxant properties. Unfortunately, the drug can be abused as a date rape drug and is sometimes nicknamed *roofies*.

History

Flunitrazepam was first synthesized in the early 1970s by Roche and was used in hospitals when deep sedation was needed. It first entered the commercial market in Europe in 1975, and in the 1980s it began to be available in other countries.

It originally came in 1 mg, 2 mg, and 5 mg sizes, but due to its potency and potential for abuse, the higher doses were taken off the market and it is now only available in 1 mg.

Pharmacology

Like other benzodiazepines, flunitrazepam's pharmacological effects include sedation, muscle relaxation, reduction in anxiety, and prevention of convulsions. However, flunitrazepam's sedative effects are approximately 7 to 10 times more potent than diazepam. The effects of flunitrazepam appear approximately 15 to 20 minutes after oral administration, and last for approximately four to six hours. Some residual effects can persist up to 12 hours or more after administration.

Medical uses

Flunitrazepam has not been approved by the Food and Drug Administration for medical use in the United States, and is considered to be an illegal drug there. It is available only by private prescription in the United Kingdom.[1] (though Rohypnol was discontinued in 1986, Rophynol use is still present in modern culture).

In the UK it is also used in some hospitals to sedate patients undergoing colonoscopy.

Prescription in Australia is restricted.[2][3] It is used primarily for the treatment of severe insomnia that has not responded to other treatments.

Rohypnol is classified as a schedule 6 drug in South Africa.[4] It is available by prescription only, and restricted to 1 mg doses. Travelers from South Africa to the United States are limited to a 30-day supply. The drug must be declared to US Customs upon arrival. If a valid prescription cannot be produced, the drug may be subject to Customs search and seizure, and the traveler may face criminal charges or deportation.

Abuse Potential

Drug-facilitated Sexual Assault

Flunitrazepam is known to induce anterograde amnesia in sufficient doses; individuals are unable to remember certain events that they experienced while under the influence of the drug. This effect is particularly dangerous when flunitrazepam is used to aid in the commission of sexual assault; victims may not be able to clearly recall the assault, the assailant, or the events surrounding the assault.

It is difficult to estimate just how many flunitrazepam-facilitated rapes have occurred in the past. Very often, biological samples are taken from the victim at a time when the effects of the drug have already passed and only residual amounts remain in the body fluids. These

residual amounts are difficult, and sometimes impossible, to detect using standard screening assays available in the United States. If flunitrazepam exposure is to be detected at all, urine samples need to be collected within 72 hours and subjected to sensitive analytical tests. The problem is compounded by the onset of amnesia after ingestion of the drug, which causes the victim to be uncertain about the facts surrounding the rape. This uncertainty may lead to critical delays or even reluctance to report the rape and provide appropriate biological samples for testing. If a person suspects that he or she is the victim of a flunitrazepam-facilitated rape, he or she should get laboratory testing for flunitrazepam as soon as possible.

It must be noted that an inability to remember events, including sexual encounters, is not conclusive evidence of having consumed a drugged drink: Drunkenness itself causes blackouts, sleepiness, and a reduction in inhibitions. Only a timely screening for flunitrazepam can demonstrate its use.

Drug-facilitated Robbery

In the United Kingdom, the use of flunitrazepam and other "date rape" drugs has been connected to stealing from sedated victims. One expert quoted in a British tabloid estimated that up to 2,000 individuals are robbed each year after being spiked with powerful sedatives [1], making drug-assisted robbery a more common problem than drug-assisted rape.

Criminals sometimes use flunitrazepam before committing robbery as it has a calming and anti-emotive effect. This allows the criminal to perform the robbery without becoming anxious. Flunitrazepam is also known to induce anterograde amnesia making police interrogations more difficult.[5][6][7]

In a notable flunitrazepam related case, Selina Hakki was found guilty in December 2004 of using flunitrazepam to drug wealthy men and rob them of their clothes and accessories in the UK.

Recreational drug

Although flunitrazepam has become widely known in USA for its use as a date-rape drug, it is used more frequently as a recreational drug. It is used by high school and college students, rave party attendees, and heroin and cocaine users (who call a dose of flunitrazepam a "roofie") for recreational purposes, including:

- To produce profound intoxication (Kurt Cobain overdosed on a mixture of flunitrazepam and champagne several weeks before his death)
- To boost the high produced by heroin, or ease the anxiety and/or sleeplessness of withdrawal
- To counteract the side effects of stimulants (e.g. insomnia, paranoia, jitteriness)
- To "soften" the so-called "crash" which follows heavy usage of stimulants, such as cocaine or methamphetamine
- To improve sex drive and appetite.

Flunitrazepam is usually consumed orally, and is often combined with alcohol. It is also occasionally insufflated (i.e. tablets are crushed into powder and snorted). In some European

countries, there was an alcohol solution of flunitrazepam (Darkene), taken by injection, with very strong effects.

Side effects

Flunitrazepam is considered to be one of the most addictive of the benzodiazepines, along with clonazepam, midazolam, temazepam, lorazepam and alprazolam. Its use causes several notable side effects, including:

- Drowsiness
- Loss of motor control
  - Dizziness
  - Lack of coordination
- Slurred speech
- Amnesia

Confusion
Gastrointestinal disturbances, lasting 12 or more hours.
Respiratory depression in higher doses

Long-term use of flunitrazepam can result in psychological and physical dependence and the appearance of withdrawal symptoms when the drug is discontinued. Flunitrazepam impairs cognitive and psychomotor functions, affecting reaction time and driving skill. The use of this drug in combination with alcohol potentiates these side effects, and can lead to toxicity.

Legal status

Flunitrazepam is currently a Schedule III drug under the international Convention on Psychotropic Substances of 1971 [2]; in the United States, it is on Schedule IV

According to FDA Associate Director for Domestic and International Drug Control Nicholas Reuter[3]:

Flunitrazepam was "temporarily controlled in Schedule IV pursuant to a treaty obligation under the 1971 Convention on Psychotropic Substances. At the time flunitrazepam was placed temporarily in Schedule IV . . . there was no evidence of abuse or trafficking of the drug in the United States."

Rophynol is currently under consideration to be rescheduled to Schedule I, and is already considered such in the States of Florida, Idaho, Minnesota, New Hampshire, New Mexico, North Dakota, Oklahoma, and Pennsylvania.

21 U.S.C. § 841 and 21 U.S.C. § 952 provide for stiff prison terms for the possession of flunitrazepam; penalties for use or distribution include life in prison, should death or serious injury occur.

In Australia, flunitrazepam is a schedule 8 drug, along with Drug Misuse and Trafficking Act 1985.

Metabolism Hepatic

Half life 10-20 hours

Excretion Renal

Therapeutic considerations

Pregnancy cat. D (USA)

Legal status Schedule IV(US)

Routes Oral, I.M., I.V., parenteral

Lorazepam (marketed under the brand names *Ativan*®, *Temesta*®, *Tavor*®) is a drug which is a benzodiazepine derivative. Pharmacologically, it is classified as a sedative-hypnotic, anxiolytic and anticonvulsant.

Trade Names: Trapax

Pharmacology and pharmacokinetics

Lorazepam is rapidly and nearly completely absorbed after any mode of application (oral, sublingual, i.m., i.v.). The onset of action is several minutes after i.v. injections, 30 to 45 minutes after oral/sublingual administration, and up to 1 hour after i.m. injections.

The duration of action depends on the dose, and is normally 6 to 12 hours. The half-life of lorazepam in patients with normal liver function is 11 to 18 hours. Therefore, 2 to 4 daily doses are often needed.

0.5mg (500μg) of lorazepam is equivalent to 5mg of diazepam [1]. Other experts estimate a proportion of 1mg lorazepam to 5mg diazepam.

Indications

Lorazepam is indicated for:

- Treatment of anxiety disorders (especially Panic Disorder)
- Short-term treatment of insomnia, particularly if associated with severe anxiety
- Treatment of symptoms associated with alcohol withdrawal
- As a premedication,
  - To facilitate unpleasant procedures, such as endoscopies and dental surgery.
  - To augment the action of the primary anaesthetic drug.
  - To produce varying degrees of anterograde amnesia for the duration of the procedure.
- Long-term treatment of otherwise resistant forms of petit mal epilepsy
- Acute therapy of status epilepticus
- Acute therapy of catatonic states alone/or with haloperidol (dangerous treatment, Lorazepam can have paradoxical effect)
- Treatment of acute delirium, preferably together with haloperidol (dangerous treatment, Lorazepam can have paradoxical effect)
- Supportive therapy of nausea/emesis frequently associated with cancer chemotherapy, usually together with firstline antiemetics like 5-HT3-antagonists
- Supportive therapy for Cyclic vomiting syndrome

Lorazepam is available in tablets and as a solution for intramuscular and intravenous injections. It is also available as a parenteral patch.

Dosage

Daily doses vary greatly, from 0.5 mg at bedtime for insomnia to 2.5 mg every 6 hours or more in the acute treatment of mania, before firstline drugs (such as lithium or valproic acid) control the situation.

Catatonia with inability to speak is very responsive and sometimes controlled with a single dose of 2 mg oral or slow i.v. injection. Catatonia may recur and treatment for some days may be necessary. Sometimes haloperidol is given concomitantly.

The control of status epilepticus requires slow i.v. injections of 2 to 4 (or even 8) mg. Patients should be closely monitored for respiratory depression and hypotensive effects.

In any case, dose requirements have to be individualized especially in the elderly and debilitated patients in whom the risk of oversedation is greater. Safety and effectiveness of lorazepam is not well determined in children under 18 years of age, but it is used to treat serial seizures. With higher doses (preferably i.v.-doses) the patient is frequently not able to recall unpleasant events (anterograde amnesia) such as therapeutic interventions (endoscopies, etc.), which is a desirable effect. But in these cases the risk is taken that a patient could later make unjustified allegations of sexual abuse during treatment due to poor recall.

After injections of lorazepam the patient should normally not be released from hospital settings without a care-giving person (parent, spouse etc.) before 24 hours have elapsed, due to incalcuable residual effects of the drug like tiredness, vertigo, hypotension etc. Also, the patient should not drive a car or handle machines for 24 hours after injection.

Disadvantages

Lorazepam, like other benzodiazepines, can cause psychological and/or physical dependence. Withdrawal symptoms similar in character to those of alcohol and barbiturates have been observed after abrupt discontinuation, therefore, a gradual taper is recommended over a period of weeks or even months, depending on the length of time it was used and the dosage taken.

The likelihood of abuse, dependence and withdrawal symptoms is substantially greater with lorazepam relative to other benzodiazepines because of its short half-life, higher potency and stronger binding to the GABA receptor complex. In this regard it behaves like alprazolam (short half-life and high potency) and clonazepam (long half-life and high potency).

Long term therapy may lead to cognitive deficits, however this is reversible upon discontinuation.

Lorazepam belongs to the Food and Drug Administration (FDA) pregnancy category D which means that it is likely to cause harm to the unborn baby, although this is very rarely seen. Lorazepam given near the time of birth may cause floppy infant syndrome and withdrawal symptoms in the infant.

In some cases there can be paradoxical effects with benzodiazepines, such as increased hostility and aggression. This is thought by some doctors to be due to disinhibition, and is therefore more likely to occur in those with preexisting personality disorders who may have less than average inhibition.

Abuse

Those with preexisting substance abuse disorders or addictive personalities are more likely to abuse medications such as lorazepam, and care should be taken when prescribing it on an outpatient basis. It is often used in an inpatient setting to assist with detox.

- Illegal use: Special data is not available but as a highly potent benzodiazepine it might be used to modulate the effects of stimulant abuse or to help with a "bad trip" caused by LSD or other hallucinogens. It can be expected that lorazepam has some street use to boost the euphoriant effects of opioids like heroin, perhaps heroin and other drugs could be "cut" with lorazepam without the knowledge of the user. The risk if used together with an opioid is respiratory depression or arrest. Its most common illegal use is simply being taken in order to "chill" from the stressors of life. Many take the drug as a "chill pill" which leads to dependency.
- Date rape drug: Lorazepam has no particular taste and could in principle be misused as a 'date rape drug' since it has strong amnesic properties relatively to other benzodiazepines. But as lorazepam has poor water solubility flunitrazepam is the more commonly used drug for this purpose. The action of lorazepam together with alcohol can be dangerous in higher amounts, causing significant central nervous system depression which manifests as unconsciousness and respiratory depression. This can lead to a coma or death.

Legal status

The patent on lorazepam held by Wyeth is expired in the United States. Generic versions of the drug are now available. Brand names include Almazine, Anxiedin, Anxira, Anzepam, Aplacasse, Aplacassee, Apo-Lorazepam, Aripax, Ativan, Azurogen, Bonatranquan, Bonton, Control, Duralozam, Efasedan, Emotion, Emotival, Kalmalin, Larpose, Laubeel, Lopam, Lorabenz, Loram, Lorans, Lorapam, Lorat, Lorax, Lorazene, Lorazep, Lorazepam, Lorazin, Lorazon, Lorenin, Loridem, Lorivan, Lorsedal, Lorzem, Lozepam, Merlit, Nervistop L, Nervistopl, NIC, Novhepar, Novolorazem, Orfidal, Punktyl, Renaquil, Rocosgen, Sedatival, Sedizepan, Sidenar, Silence, Sinestron, Somnium, Stapam, Tavor, Temesta, Titus, Tranqipam, Trapax, Trapex, Upan, Wintin, Wypax.

In 2000, the U.S. drug company Mylan agreed to pay $147 million to settle accusations by the F.T.C. that they had raised the price of generic lorazepam by 2600 percent and generic clorazepate by 3200 percent in 1998 after having obtained exclusive licensing agreements for certain ingredients.

Lorazepam is a Schedule IV drug under the Controlled Substances Act in the US and internationally under the United Nations Convention on Psychotropic Substances.

Metabolism Hepatic

Half life 1.8-6.4 hours

Excretion Renal

Therapeutic considerations

Pregnancy cat. C (USA), C (Aus)

Legal status Schedule IV(US)

Routes Oral, I.M., I.V., parenteral

Midazolam, (marketed under brand names *Versed*®, *Hypnovel*® and *Dormicum*®, pronounced mjÈdæzYlæm) is a drug which is a benzodiazepine derivative. It has powerful anxiolytic, amnestic, hypnotic, anticonvulsant, skeletal muscle relaxant and sedative properties. It is considered a fast-acting benzodiazepine, with a short elimination half-life.

Midazolam was first synthesized in 1976 by Fryer and Walser.

Pharmacology

Unlike other benzodiazepines such as diazepam and lorazepam, midazolam is water soluble because the imidazoline ring is open at pH under 4. However, when it is injected, the slightly alkaline (pH about 7.4) environment of the bloodstream causes the imidazoline ring to close, and it becomes much more lipid soluble, facilitating its rapid uptake into nerve tissue. This, and the fact that it has a pKa of 6.15 and is therefore predominantly un-ionised (>90%) at physiological pH, accounts for its rapid onset of action.

Metabolism is by the hepatic Cytochrome p450 enzyme 3A3/3A4. It is hydroxylated to the active metabolite 1-hydroxy-midazolam and then glucuronidated before being renally excreted.

Indications

Midazolam is frequently used (usually in combination with other agents, such as morphine) by anesthesia providers (nurse anesthetists and anesthesiologists) for sedating patients prior to surgery or other invasive medical procedures, such as endoscopy. The patient typically does not actually lose consciousness, but may lose the ability to form memories (anterograde amnesia).

Due to its high potency and fast onset of effects, it is rarely prescribed outside of hospitals. An exception is buccal midazolam, used for the rapid treatment of prolonged seizures. This is an off-label use usage of midazolam, although it has become increasingly common. When using it for this purpose, the drug is squirted slowly between the gums and the inside of the cheek, where it is absorbed directly into the blood stream.

- Intramuscular or intravenous:
  - Preoperative sedation, anxiolysis, amnesia,
  - Treatment of epileptic seizures.
- Intravenous:
  - For sedation, anxiolysis, and amnesia prior to endoscopic procedures. Often used in combination with other CNS depressants.
  - For general anesthesia, often in combination with other anesthetic agents.
- Continuous I.V. infusion:
  - For sedation of intubated patients in an intensive care setting.

Oral: Syrup formulation is often used for dental preoperative sedation for children.

Dosage

The dosing of midazolam is highly variable depending on other patient factors and other concurrently administered drugs.

- Preoperative anxiolysis: 0.5-2.5 mg.
- Endoscopy: 3-5 mg (rarely 10mg) IV, often paired with short acting opiods in moderate dosage. For example, 50mg pethidine or equivalent dosage of fentanyl (2.5-5 micrograms).
- Status epilepticus: 10mg intranasally or as buccal.

Side effects and abuse potential

Midazolam is categorized as a Schedule IV controlled substance, meaning it has low abuse potential compared to substances such as hydrocodone or oxycodone. As a benzodiazepine it shares similar side effects to other members of this drug family, however it is far less often abused given the ready availability of alternatives, and its primary use in hospital settings

only. The mild amnesia caused by this drug is a side effect commonly used for its effect as a 'pre-med' before surgery. Rapid infusion of midazolam may cause transient apnea, and occasionally, respiratory arrest.

Interactions

Midazolam is metabolized almost completely by cytochrome P450-3A4. Vmax in microsomes is reported as 850 pmol/min/mg microsomal protein. Km is reported as 3.7 uMol. Metabolism in the gut wall is reported as nearly equal to metabolism in liver by CYP3A4. Therefore, midazolam will interact with other 3A4 substrates and inhibitors. Grapefruit juice reduces intestinal 3A4 and results in less gut wall metabolism and higher plasma concentrations, which could result in overdose.

Contraindications

Hypersensitivity, acute narrow angle glaucoma, shock, hypotension, head injury, and drug or alcohol use.

Overdose

Symptoms of midazolam overdose include:

- Somnolence (difficulty staying awake)
- Mental confusion
- Hypotension
- Impaired motor functions
  - Impaired reflexes
  - Impaired coordination
  - Impaired balance
  - Dizziness
- Coma

In animal models, the oral LD_{50} of midazolam is 825 mg/kg.

Midazolam overdose is considered a medical emergency and generally requires the immediate attention of medical personnel. The antidote for an overdose of midazolam (or any other benzodiazepine) is flumazenil (Anexate®).

Legal status

Midazolam is a Schedule IV drug under the Convention on Psychotropic Substances.

Carboxamides

Carboxamides are drugs that can be used as anticonvulsants. In organic chemistry carboxamides (or amino carbonyls) are functional groups with the general structure R-CO-NH_2 with R as an organic substituent.

Two amino acids, asparagine and glutamine, have a carboxamide group in them.
The following are carboxamides:

- carbamazepine

oxcarbazepine

Gamma-aminobutyric acid

Gamma-aminobutyric acid (usually abbreviated to *GABA*) is an inhibitory neurotransmitter found in the nervous systems of widely divergent species. It is the chief inhibitory neurotransmitter in the vertebrate central nervous system.

Systematic name 4-aminobutanoic acid

Other names GABA

Molecular formula $C_4H_9NO_2$

SMILES C(CC(=O)O)CN

Molar mass 103.12 g/mol

Appearance white solid

CAS number 56-12-2

Properties

Solubility in water 0.5 M (20 °C)

Melting point 203°C (476 K)

Acidity (pK_a) 10.43

Basicity (pK_b) 9.77

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Action and receptors

In vertebrates, GABA acts at inhibitory synapses in the brain. GABA acts by binding to specific receptors in the plasma membrane of both pre- and postsynaptic neurons. This binding causes the opening of ion channels to allow either the flow of negatively-charged chloride ions into the cell or positively-charged potassium ions out of the cell. This will typically result in a negative change in the transmembrane potential, usually causing hyperpolarization.

Three general classes of GABA receptor are known. These include GABAA and GABAC ionotropic receptors, which are ion channels themselves, and GABAB metabotropic receptors, which are G protein-coupled receptors that open ion channels via intermediaries (G proteins).

Neurons that produce GABA as their output are called GABAergic neurons, and have chiefly inhibitory action at receptors in the vertebrate. Medium Spiny Cells are a typical example of inhibitory CNS GABAergic cells. GABA exhibits excitatory actions in insects, mediating muscle activation at synapses between nerves and muscle cells and also the stimulation of certain glands. GABA has also been shown to have excitatory roles in the vertebrate, most notably in the developing cortex.

Synthesis

Organisms synthesize GABA from glutamate using the enzyme L-glutamic acid decarboxylase and pyridoxal phosphate as a cofactor. It is worth noting that this involves converting the principal excitatory neurotransmitter (glutamate) into the principal inhibitory one (GABA).

Pharmacology

Drugs that act as agonists of GABA receptors (known as GABA analogues or GABAergic drugs) or increase the available amount of GABA typically have relaxing, anti-anxiety and anti-convulsive effects. Many of the substances below are known to cause short-term memory loss and retrograde amnesia.

Drugs that affect GABA receptors:

- avermectins — doramectin, selamectin, ivermectin
- barbiturates
- bicucullines
- benzodiazepines
- baclofen
- tramadol
- opiates
- cannabinoids

- carbamazepines

cyclopyrrolone derivatives — eszopiclone, zopiclone
ethanol [1] [2]

- fluoroquinolones

- gabazine (SR-95531)

gamma-hydroxybutyrate (GHB) [3]

- imidazopyridines — zaleplon, zolpidem
- muscimol

phenytoin
picrotoxin
progabide
propofol
phenibut
thujone
valproate

Drugs that affect GABA in other ways:

- tiagabine - potentiates by inhibiting uptake into neurons and glia
- vigabatrin - potentiates by inhibiting GABA-T, preventing GABA breakdown

Potassium bromide

Molecular formula KBr

Molar mass 119.01 g/mol

Appearance white solid

CAS number [7758-02-3]

Properties

Density and phase 2.75 g/cm3, solid

Solubility in water 53.5 g/100 ml (0 °C)

Solubility in ethanol 0.142 g/100 ml (25 °C)

Melting point 734 °C (1007 K)

Boiling point 1435 °C (1708 K)

Structure

Coordination geometry octahedral

Crystal structure Sodium chloride

Dipole moment 10.41 D (gas)

Related compounds

Other anions Potassium fluoride, Potassium chloride, Potassium iodide

Other cations Lithium bromide, Sodium bromide, Rubidium bromide, Caesium bromide

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Potassium bromide (KBr) is a salt, widely used as an anticonvulsant and a sedative in the late 19th and early 20th centuries. Its action is due to the bromide ion (sodium bromide is equally effective). Potassium bromide is presently used as veterinary drug, as an antiepileptic medication for dogs and cats. It is a white crystalline powder, soluble in water. In a dilute aqueous solution, potassium bromide tastes sweet, at higher concentration it tastes bitter, and when most concentrated it tastes salty to humans (these effects are due mainly to potassium ion; sodium bromide merely tastes salty at all concentrations). In high concentration potassium bromide strongly irritates the gastric mucous membrane, leading to nausea and sometimes vomiting (again this effect is typical of all soluble potassium salts).

Chemical properties

Potassium bromide is a typical ionic salt which is fully dissociated and near pH 7 in aqueous solution. It serves as a source of bromide ions- this reaction is important for the manufacture of silver bromide for photographic film:

KBr(aq) + AgNO3(aq) ’ AgBr(s) + KNO3(aq)

Aqueous bromide Br- will also form complexes when reacted with some metal halides such as copper(II) bromide:

2 KBr(aq) + CuBr2(aq) ’ K2[CuBr4](aq)

Preparation

A traditional method for the manufacture of KBr is the reaction of potassium carbonate with a bromide of iron, Fe3Br8, made by treating scrap iron under water with excess Br2:

4 K2CO3 + Fe3Br8 ’ 8 KBr + Fe3O4 + 4 CO2

Uses

Medical and Veterinary

The anticonvulsant properties of potassium bromide were first noted by Sir Charles Locock at a meeting of the Royal Medical and Chirurgical Society in 1857. Bromide can be regarded as the first effective medication for epilepsy. At the time, it was commonly thought that epilepsy was caused by masturbation. Locock noted that bromide calmed sexual excitement and thought this was responsible for his success in treating seizures. There would not be a better drug for epilepsy until phenobarbital in 1912.

Potassium bromide is used to treat epilepsy in dogs, either as first-line treatment or in addition to phenobarbital when the seizures are not adequately controlled with phenobarbital alone. Use of bromide in cats is limited because it carries a substantial risk of causing lung inflammation (pneumonitis) in this species.

Potassium bromide is not approved by the US Food and Drug Administration (FDA) for use in humans to control seizures. In Germany it continues to be approved for use as an antiepileptic drug for humans, particularly children and aldolescents. These indications include severe forms of generalized tonic-clonic seizures, early-childhood-related Grand-Mal-seizures, and also severe myoclonic seizures during childhood. Adults who have reacted positively to the drug during childhood/adolescence may continue treatment. KBr is sold under the brand name Dibro-Be mono® (RX-only). When used for proper indications it shows promising results. The drug has almost complete bioavailability and an extremely long half-life of 6 weeks. One tablet contains 850 mg of potassium bromide. Potassium bromide is not known to interfere with the absorption or excretion of any other anticonvulsant.

The therapeutic index is very small for bromide. As with other antiepileptics, sometimes even therapeutic doses give rise to intoxication. Often indistinctable from 'expected' side-effects, these include:

- Loss of appetite, nausea/emesis, lethargy, propensity to sleep during the daytime, depression, loss of concentration and memory, confusion, headache, and
- bromism (central reactions reaching from somnolence to coma, cachexia, exicosis, loss of reflexes or pathologic reflexes, clonic seizures, tremor, ataxia, loss of neural sensitivity, paresis, papillar edema of the eyes, abnormal speech, cerebral edema, frank delirium, aggressivity, psychoses)
- Acne-form dermatitis and other forms of skin disease may also be seen, as well as mucous hypersecretion in the lungs. Asthma and rhinitis may worsen. Rarely, tongue disorder, aphten, bad breath, and obstipation occur.

Optics

KBr is transparent from the near ultraviolet to long wave infrared wavelengths (0.25-25 μm). It is used for optical windows and prisms. It must be kept in a dry environment due to high solubility and hygroscopic nature. The refractive index is about 1.55 at 1.0 μm. When measuring an infrared transmission spectrum it is a common practice to mix a sample with

KBr powder and press the sample into a disk. KBr has no significant optical absorption lines in its high transmission region.

Antidotes

An *antidote* is a substance which can counteract a form of poisoning.

Sometimes, the antidote for a particular toxin is manufactured by injecting the toxin into an animal in small doses and the resulting antibodies are extracted from the animals' blood. The venom produced by some snakes, spiders, and other venomous animals is often treatable by the use of these antivenoms, although a number do lack one, and a bite or sting from such an animal often results in death.

However, some toxins have no known antidote. For example, the poison ricin, which is produced from the waste byproduct of castor oil manufacture, has no antidote, and as a result is often fatal if it enters the human body in sufficient quantities.

Ingested poisons are frequently treated by the oral administration of activated charcoal, which adsorbs the poison, and then it is flushed from the digestive tract, removing a large part of the toxin.

Poisons which are injected into the body (such as those from bites or stings from venomous animals) are usually treated by the use of a constriction band which limits the flow of lymph and/or blood to the area, thus slowing circulation of the poison around the body.

Poison and Toxic Signs

- Acetaminophen (paracetamol) poisoning is given N-acetylcysteine as the antidote.

Anticholinergic poisoning is given Physostigmine sulfate as the antidote.
Benzodiazepine poisoning is given flumazenil as the antidote.
Carbon monoxide poisoning is given oxygen as the antidote.
Anticholinesterase poisoning is given atropine sulfate and Pralidoxime chloride 2-PAM as the antidote.
Cyanide poisoning is given amyl nitrite, sodium nitrite, and thiosulfate as the antidote.
Digoxin poisoning is given anti digoxin fab fragments as the antidote.
Ethylene glycol poisoning is given ethanol or fomepizole as the antidote.
Extrapyramidal signs poisoning is given diphenhydramine hydrochloride and benztropine mesylate as the antidote.
Heavy metal poisoning is given chelators, calcium disodium edetate (EDTA), dimercaprol (BAL), penicillamine, and 2,3-dimercaptosuccinic acid (DMSA, succimer) as the antidote.
Iron poisoning is given deferoxamine mesylate as the antidote.
Isoniazid poisoning is given pyridoxine as the antidote.
Methanol poisoning is given ethanol or fomepizole as the antidote.
Methemoglobinemia poisoning is given methylene blue as the antidote.
Opioid poisoning is given naloxone hydrochloride as the antidote.

Warfarin poisoning is given vitamin K phytonadione and fresh frozen plasma as the antidote.

Poison

In the context of biology, *poisons* are substances that can cause injury, illness, or death to organisms, usually by chemical reaction or other activity on the molecular scale, when a sufficient quantity is absorbed by an organism. Paracelsus, the father of toxicology states--"Everything is poison, there is poison in everything. Only the dose makes a thing not a poison".

In medicine (particularly veterinary) and in zoology, a poison is often distinguished from a venom. Venoms are usually defined as biologic toxins that are injected to cause their effect, while poisons are generally defined as substances which are absorbed through epithelial linings such as the skin or gut.

Terminology

Some poisons are also toxins, usually referring to naturally produced substances, such as the bacterial proteins that cause tetanus and botulism. A distinction between the two terms is not always observed, even among scientists.

Animal toxins that are delivered subcutaneously (e.g. by sting or bite) are also called venom. In normal usage, a poisonous organism is one that is harmful to consume, but a venomous organism uses poison to defend itself while still alive. A single organism can be both venomous and poisonous.

The derivative forms "toxic" and "poisonous" are synonymous.

Within chemistry and physics, a poison is a substance that obstructs or inhibits a reaction, for example by binding to a catalyst.

Lay use

The phrase "poison" is often used colloquially to describe any harmful substance:

- Carcinogens, such as some artificial sweeteners, Asbestos, Benzene, Carbon tetrachloride, Dioxin, and tobacco

Mutagens, such as Ultraviolet rays (Long term exposure may cause skin cancer such as Melanoma) and other Ionizing Radiation (causes radiation sickness and cancer)

Teratogens, such as Thalidomide

Pollutants can be poisonous, or they can be non-poisonous but harmful in other ways.

Warning symbols

Poisons have been known to be symbolized by the skull and crossbones, indicating lethal potential. This is the UN standard symbol, used in the European Union. However, it can be considered a liability for marketing. In the United States, other symbols such as Mr. Yuk are replacing the skull and crossbones. Proponents of the Mr. Yuk argue that the skull-and-crossbones symbols attracts children because of its association to pirates, and assert that Mr. Yuk does not.

Chemicals with non-lethal hazards, such as corrosivity, mild toxicity and harmfulness, may be informally referred to as "poisons", but are not usually marked with the skull-and-crossbones symbol. To contrast, see also the definitions of corrosive, harmful, environmentally hazardous and irritant. The UN standard symbol for harmful and irritant substances is an 'X' on an orange background. This is applied to materials with non-lethal hazards as well as to potentially lethal materials.

Uses of poison

The uses of poisons specifically because of their toxicity is limited. Applications have been mainly for controlling pests and weeds, and for preserving building materials and food stuffs. Where possible, specific agents which are less poisonous to humans have come to be preferred, but exceptions such as phosphine continue in use.

Throughout human history, intentional application of poison has been used as a method of assassination, murder, suicide and execution. As a method of execution, poison has been ingested, as the ancient Athenians did (see Socrates), inhaled, as with carbon monoxide or hydrogen cyanide (see gas chamber), or injected (see lethal injection). Many languages describe lethal injection with their corresponding words for "poison shot".

Poisonous materials are often used for their chemical or physical properties other than being poisonous. The most effective, easiest, safest, or cheapest option for use in a chemical synthesis may be a poisonous material. Particularly in experimental laboratory syntheses a specific reactivity is used, despite the toxicity of the reagent. Chromic acid is an example of such a "simple to use" reagent. Many technical applications call for some specific physical properties; a toxic substance may possess these properties and therefore be superior. Reactivity, in particular, is important. Hydrogen fluoride, for example, is poisonous and extremely corrosive. However, it has a high affinity for silicon, which is exploited by using HF to etch glass or to manufacture silicon semiconductor chips.

Biological poisoning

Acute poisoning is exposure to a poison on one occasion or during a short period of time. Symptoms develop in close relation to the exposure.

Chronic poisoning is long-term repeated or continuous exposure to a poison where symptoms do not occur immediately or after each exposure. The patient gradually becomes ill, or becomes ill after a long latent period. Chronic poisoning most commonly occurs following exposure to poisons that bioaccumulate such as mercury and lead.

Contact or absorption of poisons can cause rapid death or impairment. Agents that act on the nervous system can paralyze in seconds or less, and include both biologically derived neurotoxins and so-called nerve gases, which may be synthesized for warfare or industry.

Inhaled or ingested cyanide as used as method of execution on US gas chambers almost instantly starves the body of energy by inhibiting the enzymes in mitochondria that make ATP. Intravenous injection of an unnaturally high concentration of potassium chloride, such as in the execution of prisoners in parts of the United States, quickly stops the heart by eliminating the cell potential necessary for muscle contraction.

Most (but not all) pesticides are created to act as poisons to target organisms, although acute or less observable chronic poisoning can also occur in non-target organism, including the humans who apply the pesticides and other beneficial organisms.

Many substances regarded as poisons are toxic only indirectly. An example is "wood alcohol" or methanol, which is not poisonous itself, but is chemically converted to toxic formaldehyde and formic acid in the liver. Many drug molecules are made toxic in the liver, and the genetic variability of certain liver enzymes makes the toxicity of many compounds differ between individuals.

The study of the symptoms, mechanisms, treatment and diagnosis of biological poisoning is known as toxicology.

Exposure to radioactive substances can produce radiation poisoning, an unrelated phenomenon.

Poisoning in humans

Children

- Poisoning is the fourth most common cause of accidental deaths in children.
- Children less than 5 years of age, as well as adolescents, are prone to poisoning.
- Accidental ingestions are most common in children less than 5 years old.
- 90% of all poisonings occur at home, the most common site being the kitchen and the bathroom.
- Unintentional poisonings occur most frequently when routines are disrupted, for example moving and vacations.
- Child safety caps have helped decrease the number of poisonings; however, they are not 100% effective and should not give a false sense of security.
- All potential poisons should be properly labeled, stored out of reach of children, and locked.
- Adolescent ingestions are more typically a result of suicidal attempts or experimentation with illicit drugs.
- Parents should receive anticipatory guidance regarding poisonings and should have the number to reach their local poison control center available, in

the USA the phone number is 1-800-222-1222. Poison control centers are free, 24 hours, and confidential.

Poisoning management

- Poison Control Centers (In the US reachable at 1-800-222-1222 at all hours) provide immediate, free, and expert treatment advice and assistance over the telephone in case of suspected exposure to poisons or toxic substances.

General first aid

- If the poison is an inhalant, remove the patient from the area and to fresh air.
- If the poisoning is affecting the skin, remove the clothing and wash the skin thoroughly unless a dry powder is the cause of the poisoning.
- If the poison is in the eye, flush the eye thoroughly for at least 15 minutes.
- Following ingestion, ensure the person remains calm, do not induce vomiting, small fluids are recommended for corrosive substances (e.g. household cleaners).
- Following these measures a poison control center can be contacted for advice on what to do next.

Initial medical management

- Initial management for all poisonings includes ensuring adequate cardiopulmonary function and providing treatment for any symptoms such as seizures, shock, and pain.

Decontamination

- The goal of gastric decontamination is to prevent absorption of the toxin. This may be achieved using activated charcoal, whole bowel irrigation, or nasogastric aspiration. Gastric lavage, cathartics, emesis, or Ipecac are no longer routinely recommended.
    - Activated charcoal is the treatment of choice to prevent absorption of the poison. It is usually administered when the patient is in the emergency room. However, charcoal is ineffective against metals, Na, K, alcohols, glycols, acids, and alkalis.

    Whole bowel irrigation cleanses the bowel, this is achieved by giving the patient large amounts of a polyethylene glycol solution. The osmotically balanced polyethylene glycol solution is not absorbed into the body, having the effect of flushing out the entire gastrointestinal tract. Its major uses are following ingestion of sustained release drugs, toxins that are not absorbed by activated charcoal (i.e. lithium, iron), and for the removal of ingested packets of drugs (body packing/smuggling).[1]

Nasogastric aspiration involves the placement of a tube via the nose down into the stomach, the stomach contents are then removed via suction. This procedure is mainly used for liquid ingestions where activated charcoal is ineffective, i.e. ethylene glycol.

Gastric lavage, commonly known as a stomach pump, is the insertion of a tube through the mouth down into the stomach, followed by administration of water or saline down the tube, the liquid is then removed again, having the overall effect of removing the contents of the stomach. Lavage has been used for many years as an initial treatment for poisoned patients, however, a recent review of the procedure for poison ingestions suggested lavage should no longer be employed routinely, if ever, in the management of poisoned patients.[2] It is still sometimes performed if it can be performed within 1 h of ingestion and the dose is potentially life threatening.

Emesis (i.e. induced by ipecac) is no longer recommended in poisoning situations.[3]

Cathartics were postulated to decrease absorption by increasing the expulsion of the poison from the gastrointestinal tract. There are two types of cathartics used in poisoned patients; saline cathartics (sodium sulfate, magnesium citrate, magnesium sulfate) and saccharide cathartics (sorbitol). They do not appear to improve patient outcome and are no longer recommended.[4]

Antidotes

Some poisons have specific antidotes:

Poison/Drug - Antidote

paracetamol - acetylcysteine

Vitamin K anticoagulants - vitamin K

opioids - naloxone

iron (and other heavy metals) - deferoxamine

benzodiazepines **- flumazenil**

ethylene glycol - ethanol or fomepizole

methanol - ethanol or fomepizole

cyanide - amyl nitrite, sodium nitrite & sodium thiosulfate

Enhanced excretion

- In some situations elimination of the poison can be enhanced using diuresis, hemodialysis, hemoperfusion, peritoneal dialysis, or exchange transfusion.

Further treatment

- In the majority of poisonings the mainstay of management is providing supportive care for the patient, i.e. treating the symptoms rather than the poison.

Types of poisons

The majority of this section is sorted by ICD-10 code, which classifies poisons based upon the nature of the poison itself. However, it is also possible to classify poisons based upon the effect the poison has (for example, "Metabolic poisons" such as Antimycin, Malonate, and 2,4-Dinitrophenol act by adversely disrupting the normal metabolism of an organism.)

(T36-T50) Poisoning by drugs, medicaments and biological substances

(T36.) Poisoning by systemic antibiotics

(T37.) Poisoning by other systemic anti-infectives and antiparasitics

(T38.) Poisoning by hormones and their synthetic substitutes and antagonists, not elsewhere classified

(T39.) Poisoning by nonopiod analgesics, antipyretics and antirheumatics

(T40.) Poisoning by narcotics and psychodysleptics (hallucinogens)

(T41.) Poisoning by anaesthetics and therapeutic gases

(T42.) Poisoning by antiepileptic, sedative-hypnotic and antiparkinsonism drugs

(T43.) Poisoning by psychotropic drugs, not elsewhere classified

(T44.) Poisoning by drugs primarily affecting the autonomic nervous system Neurotoxins interfere with nervous system functions and often lead to near-instant paralysis followed by rapid death. They include most spider and snake venoms, as well as many modern chemical weapons. One class of toxins of interest to neurochemical researchers are the various cone snail toxins known as conotoxins.

- Atropine

  - Poison hemlock

Anticholinesterases (T44.0)

  - Fasciculin

- Nerve agents

Acetylcholine antagonists

- Curare
- Pancuronium

Cell membrane disrupters Others

- Nicotine - not strictly a neurotoxin, but capable in large doses of causing heart attack

(T45.) Poisoning by primarily systemic and haematological agents, not elsewhere classified

- Phytohaemagglutinin (Red kidney bean poisoning)

(T46.) Poisoning by agents primarily affecting the cardiovascular system

- Digitoxin
- Digoxin
- Ouabain

(T47.) Poisoning by agents primarily affecting the gastrointestinal system

- Solanine

Hyoscyamine

(T48.) Poisoning by agents primarily acting on smooth and skeletal muscles and the respiratory system

- Strychnine

Aconite

(T49.) Poisoning by topical agents primarily affecting skin and mucous membrane and by ophthalmological, otorhinolaryngological and dental drugs

(T50.) Poisoning by diuretics and other unspecified drugs, medicaments and biological substances

(T51-T65) Toxic effects of substances chiefly nonmedicinal as to source

(T51.) Toxic effect of alcohol

- (T51.0) Ethanol
- (T51.1) Methanol

(T52.) Toxic effect of organic solvents

(T53.) Toxic effect of halogen derivatives of aliphatic and aromatic hydrocarbons

(T54.) Toxic effect of corrosive substances Corrosives mechanically damage biological systems on contact. Both the sensation and injury caused by contact with a corrosive resembles a burn injury.

- Acids and bases, corrosives
  - Various light metal oxides, hydroxides, superoxides
  - Bleach, some pool chemicals, other hypochlorates (acidic and oxydizing effect)
  - Hydrofluoric acid

Acids (T54.2) Strong inorganic acids, such as concentrated sulfuric acid, nitric acid or hydrochloric acid, destroy any biological tissue with which they come in contact within seconds.

Bases (T54.3) Strong inorganic bases, such as lye, gradually dissolve skin on contact but can cause serious damage to eyes or mucous membranes much more rapidly. Ammonia is a

far weaker base than lye, but has the distinction of being a gas and thus may more easily come into contact with the sensitive mucous membranes of the respiratory system. Quicklime, which has household uses, is a particularly common cause of poisoning. Some of the light metals, if handled carelessly, can not only cause thermal burns, but also produce very strongly basic solutions in sweat.

(T55.) Toxic effect of soaps and detergents

(T56.) Toxic effect of metals A common trait shared by heavy metals is the chronic nature of their toxicity (a notable exception would be bismuth, which is considered entirely non-toxic). Low levels of heavy metal salts ingested over time accumulate in the body until toxic levels are reached.

Heavy metals are generally far more toxic when ingested in the form of soluble salts than in elemental form. For example, metallic mercury passes through the human digestive tract without interaction and is commonly used in dental fillings—even though mercury salts and inhaled mercury vapor are highly toxic.

Examples:

- (T56.0) Lead poisoning
- (T56.1) Mercury
- (T56.2) Chromium
- (T56.3) Cadmium
- (T56.7) Beryllium (a highly but subtly toxic light metal)
- Antimony
- Barium
- Thallium
- Uranium

(T57.) Toxic effect of other inorganic substances

- (T57.0) Arsenic
  - Arsenic compounds
    - Arsenic trioxide

Fowler's solution

Reducing agents

- (T57.1) The most notable substance in this class is phosphorus.

(T58.) Toxic effect of carbon monoxide

- (T58) By far the most notable metabolic poison is carbon monoxide, which blocks the ability of red blood cells to transport oxygen.

(T59.) Toxic effect of other gases, fumes and vapours

- Formaldehyde (T59.2)

Phosgene

Phosphine

Hydrogen sulfide

Oxidizers Poisons of this class are generally not very harmful to higher life forms such as humans (for whom the outer layer of cells are more or less disposable), but lethal to microorganisms such as bacteria. Typical examples are ozone and chlorine (T59.4), either of which is added to nearly every municipal water supply in order to kill any harmful microorganisms present.

All halogens are strong oxidizing agents, fluorine (T59.5) being the strongest of all.
(T60.) Toxic effect of pesticides

- Pesticide poisoning

Fluoroacetate is a metabolic poison that blocks a vital step in the citric acid cycle.
Rotenone is a metabolic poison that disrupts electron transport in cellular respiration.

(T61.) Toxic effect of noxious substances eaten as seafood

- Ciguatera poisoning

Scombroid poisoning
Shellfish toxins (PSP, DSP, NSP, ASP)
Domoic acid (or Amnesic Shellfish Poison, ASP)
Tetrodotoxin

(T62.) Toxic effect of other noxious substances eaten as food

- Food poisoning

Botulin toxin
Hemlock water dropwort
Grayanotoxin (Honey intoxication)
Tetanospasmin (Tetanos Toxin)

(T63.) Toxic effect of venomous animals

- Snake and spider venoms

(T64.) Toxic effect of aflatoxin and other mycotoxin food contaminants

- Fungal toxins
  - Amanita toxin
  - Muscarine
  - Aflatoxins

(T65.) Toxic effect of other and unspecified substances

- (T65.0) Cyanide is a metabolic poison that bonds with an enzyme involved in ATP production.

Antihistamines

An *antihistamine* is a drug which serves to reduce or eliminate effects mediated by histamine, an endogenous chemical mediator released during allergic reactions, through action at the histamine receptor. Only agents where the main therapeutic effect is mediated by negative modulation of histamine receptors are termed antihistamines - other agents may have antihistaminergic action but are not true antihistamines.

In common use, the term antihistamine refers only to *H1-receptor antagonists*, also known as *H1-antihistamines*. It has been discovered that these H***1***-antihistamines are actually inverse agonists at the histamine H***1***-receptor, rather than antagonists per se. (Leurs, Church & Taglialatela, 2002)

Pharmacology

In allergic reactions an allergen (a type of antigen) interacts with and cross-links surface IgE antibodies on mast cells and basophils. Once the mast cell-antibody-antigen complex is formed, a complex series of events occurs that eventually leads to cell-degranulation and the release of histamine (and other chemical mediators) from the mast cell or basophil. Once released, histamine can react with local or widespread tissues through histamine receptors.

Histamine, acting on H***1***-receptors, produces pruritus, vasodilatation, hypotension, flushing, headache, tachycardia, bronchoconstriction, increases vascular permeability, potentiates pain, and more. (Simons, 2004)

While H***1***-antihistamines ameliorate these effects, they are only efficacious if administered prior to the allergen-challenge. In severe allergies, such as anaphylaxis or angioedema, these effects may be so severe as to be life-threatening.

Clinical use of antihistamines

Indications

H***1***-antihistamines are clinically used in the treatment of histamine-mediated allergic conditions. Specifically, these indications may include: (Rossi, 2004)

- allergic rhinitis
- allergic conjunctivitis
- allergic dermatological conditions (contact dermatitis)
- urticaria
- angioedema
- pruritus (atopic dermatitis, insect bites)
- anaphylactic or anaphylactoid reactions - adjunct only
- nausea and vomiting (first-generation H1-antihistamines)
- sedation (first-generation H1-antihistamines)

Antihistamines can be administered topically (through the skin, nose, or eyes) or systemically, based on the nature of the allergic condition.

Adverse drug reactions

Adverse drug reactions are most commonly associated with the first-generation H***1***-antihistamines. This is due to their relative lack of selectivity for the H***1***-receptor.

The most common adverse effect is sedation; this "side effect" is utilised in many OTC sleeping-aid preparations. Other common adverse effects in first-generation H1-antihistamines include: dizziness, tinnitus, blurred vision, euphoria, uncoordination, anxiety, insomnia, tremor, nausea and vomiting, constipation, diarrhoea, dry mouth, and dry cough. Infrequent adverse effects include: urinary retention, palpitations, hypotension, headache, hallucination, and psychosis. (Rossi, 2004)

The newer second-generation H***1***-antihistamines are far more selective for peripheral histamine H***1***-receptors and, correspondingly, have a far improved tolerability profile compared to the first-generation agents. The most common adverse effects noted for second-generation agents include: drowsiness, fatigue, headache, nausea and dry mouth. (Rossi, 2004)

First-generation H*1*-receptor antagonists

These are the oldest antihistaminergic drugs and are relatively inexpensive and widely available. They are effective in the relief of allergic symptoms, but are typically moderately to highly potent muscarinic acetylcholine receptor-antagonists (anticholinergic) agents as well. These agents also commonly have action at ±-adrenergic receptors and/or 5-HT receptors. This lack of receptor-selectivity is the basis of the poor tolerability-profile of some of these agents, especially compared with the second-generation H***1***-antihistamines. Patient response and occurrence of adverse drug reactions vary greatly between classes and between agents within classes.

The first H***1***-antihistamine discovered was piperoxan, by Forneau and Daniel Bovet (1933) in their efforts to develop a guinea pig animal-model for anaphylaxis. Bovet went on to win the 1957 Nobel Prize in Physiology or Medicine for his contribution. Following their discovery, the first-generation H***1***-antihistamines were developed in the following decades. They can be classified on the basis of chemical structure, and agents within these groups have similar properties.

Ethylenediamines

Ethylenediamines were the first group of clinically-effective H***1***-antihistamines developed.

- mepyramine (pyrilamine) antazoline

Ethanolamines

Diphenhydramine was the prototypical agent in this group. Significant anticholinergic adverse effects, including sedation, are observed in this group but the incidence of gastrointestnal adverse effects is relatively low. (Nelson, 2002; Rossi, 2004)

- diphenhydramine

carbinoxamine
doxylamine
clemastine
dimenhydrinate

Alkylamines

The isomerism is a significant factor in the activity of the agents in this group. E-triprolidine, for example, is 1000-fold more potent than Z-triprolidine. This difference relates to the positioning and fit of the molecules in the histamine H1-receptor binding site. (Nelson, 2002) Alkylamines are considered to have relatively fewer sedative and gastrointestinal adverse effects, but relatively greater incidence of paradoxical CNS stimulation. (Rossi, 2004)

- pheniramine

chlorphenamine (chlorpheniramine)
dexchlorphenamine
brompheniramine
triprolidine

Piperazines

These compounds are structurally-related to the ethylenediamines and the ethanolamines; and produce significant anticholinergic adverse effects. Compounds from this group are often used for motion sickness, vertigo, nausea and vomiting. The second-generation H***1***-antihistamine cetirizine also belongs to this chemical group. (Nelson, 2002)

- cyclizine

chlorcyclizine
hydroxyzine
meclizine

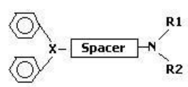
Tricyclics

These compounds differ from the phenothiazine antipsychotics in the ring-substitution and chain characteristics. (Nelson, 2002) They are also structurally-related to the tricyclic antidepressants, explaining the antihistaminergic adverse effects of those two drug classes and also the poor tolerability profile of tricyclic H***1***-antihistamines. The second-generation H***1***-antihistamine loratadine was derived from compounds in this group.

- promethazine
alimemazine (trimeprazine)
cyproheptadine
azatadine
ketotifen

Common structural features of classical antihistamine

- 2 Aromatic rings, connected to a central Carbon, Nitrogen or CO
- Spacer between the central X and the amine, usually 2-3 carbons in length, linear, ring, branched, saturated or unsaturated
- Amine is substituted with small alkyl groups eg CH3



X = N, R1 = R2 = small alkyl groups
X = C
X = CO

- Chirality at X can increase both the potency and selectivity for H1-receptors
- For maximum potency, the two aromatic rings should be orientated in different planes.
  - for example, tricyclic ring system is slightly puckered and the two aromatic rings lie in different geometrical planes, giving the drug a very high potency.

Second-generation H*1*-receptor antagonists

These are newer drugs that are much more selective for peripheral H***1*** receptors in preference to the central nervous system histaminergic and cholinergic receptors. This selectivity significantly reduces the occurrence of adverse drug reactions compared with first-generation agents, while still providing effective relief of allergic conditions.

Systemic

- acrivastine
astemizole
cetirizine
loratadine
mizolastine
terfenadine (withdrawn from most markets due to risk of cardiac arrhythmias and replaced with fexofenadine)

Topical

- azelastine
levocabastine
olopatadine

Common structural features of non-sedating antihistamines

Structure of these drugs varies from case to case. There is no common structural feature for the second generation H1-receptor antagonists.

Third-generation H*1*-receptor antagonists

These are the active enantiomer (levocetirizine) or metabolite (desloratadine & fexofenadine) derivatives of second-generation drugs intended to have increased efficacy with fewer adverse drug reactions. Indeed, fexofenadine is associated with a decreased risk of cardiac arrhythmia compared to terfenadine. However, there is little evidence for any advantage of levocetirizine or desloratadine, compared to cetirizine or loratadine respectively.

Systemic

- levocetirizine
desloratadine
fexofenadine

Other agents

Inhibitors of histamine release

These agents appear to stabilise the mast cells to prevent degranulation and mediator release.

- cromoglicate (cromolyn)
nedocromil

H_2-receptor antagonists

Main article: H2-receptor antagonist

Clinically-relevant histamine H***2***-receptors are found principally in the parietal cells of the gastric mucosa. H2-receptor "antagonists" are also inverse agonists, rather than true antagonists; and are used to reduce the secretion of gastric acid. Examples include cimetidine, ranitidine, and famotidine.

H_3- and H_4-receptor antagonists

These are experimental agents and do not yet have a defined clinical use.

H*3*-receptors antagonists

- Thioperamide

Clobenpropit

- Impromidine
  - Similar in structure to burimamide

imidazole ring

Polar moiety on the side chain - thiourea, isothiourea and guanidine

other substituents are highly variable

H*4*-receptors antagonists

- Thioperamide

Other agents with antihistaminergic activity

Many drugs, used for other indications, possess unwanted antihistaminergic activity. These include tricyclic antidepressants, antipsychotics, etc.

H2-receptor antagonists

An *H2-receptor antagonist*, often shortened to *H2 antagonist*, is a drug used to block the action of histamine on parietal cells in the stomach, decreasing acid production by these cells. These drugs are used in the treatment of dyspepsia, however their use has waned since the advent of the more effective proton pump inhibitors.

Like the H_1-antihistamines, the H***2*** antagonists are inverse agonists rather than true receptor antagonists.

History and development

Cimetidine was the prototypical histamine H2-receptor antagonist from which the later members of the class were developed. Cimetidine was the culmination of a project at Smith, Kline & French (SK&F; now GlaxoSmithKline) to develop a histamine receptor antagonist to suppress stomach acid secretion.

At the time (1964) it was known that histamine was able to stimulate the secretion of stomach acid, but also that traditional antihistamines had no effect on acid production. In the process, the SK&F scientists also proved the existence of histamine H***2*** receptors.

The SK&F team used a rational drug-design structure starting from the structure of histamine - the only design lead, since nothing was known of the then hypothetical H***2*** receptor. Hundreds of modified compounds were synthesised in an effort to develop a model of the receptor. The first breakthrough was $N_{\pm}$-guanylhistamine, a partial H***2***-receptor antagonist. From this lead the receptor model was further refined and eventually led to the development of burimamide - the first H2-receptor antagonist. Burimamide, a specific competitive antagonist at the H***2*** receptor 100-times more potent than $N_{\pm}$-guanylhistamine, proved the existence of the H***2*** receptor.

Burimamide was still insufficiently potent for oral administration and further modification of the structure, based on modifying the pKa of the compound, lead to the development of metiamide. Metiamide was an effective agent, however it was associated with unacceptable nephrotoxicity and agranulocytosis. It was proposed that the toxicity arose from the thiourea group, and similar guanidine-analogues were investigated until the ultimate discovery of Cimetidine (common brand name Tagamet).

Ranitidine (common brand name Zantac) was developed by Glaxo (also now GlaxoSmithKline) in an effort to match the success of Smith, Kline & French with cimetidine. Ranitidine was also the result of a rational drug-design process utilising the, by then, fairly refined model of the histamine H2 receptor and quantitative structure-activity relationships (QSAR).

Glaxo refined the model further by replacing the imidazole-ring of cimetidine with a furan-ring with a nitrogen-containing substituent, and in doing so developed ranitidine. Ranitidine was found to have a far-improved tolerability profile (i.e. fewer adverse drug reactions), longer-lasting action, and ten times the activity of cimetidine.

Ranitidine was introduced in 1981 and was the world's biggest-selling prescription drug by 1988. The H***2***-receptor antagonists have since largely been superseded by the even more

effective proton pump inhibitors, with omeprazole becoming the biggest-selling drug for many years.

Pharmacology

The H2 antagonists are competitive inhibitors of histamine at the parietal cell H2 receptor. They suppress the normal secretion of acid by parietal cells and the meal-stimulated secretion of acid. They accomplish this by two mechanisms: histamine released by ECL cells in the stomach is blocked from binding on parietal cell H2 receptors which stimulate acid secretion, and other substances that promote acid secretion (such as gastrin and acetylcholine) have a reduced effect on parietal cells when the H2 receptors are blocked.

Clinical use of H2-antagonists

Indications

H2-antagonists are clinically used in the treatment of acid-related gastrointestinal conditions. Specifically, these indications may include: (Rossi, 2005)

- peptic ulcer disease (PUD)

gastroesophageal reflux disease (GERD)
dyspepsia
stress ulcer prophylaxis (raniditine)

People that suffer from heartburn (GERD) infrequently may take either antacids or H2-receptor antagonists for treatment. H2-antagonists offer several advantages over antacids including longer duration of action (6–10 hours vs 1–2 hours for antacids), greater efficacy, and ability to be used prophylactically before meals to reduce the chance of heartburn occurring. Proton pump inhibitors, however, are the preferred treatment for erosive oesophagitis since they have been shown to promote healing better than H2-antagonists.

Some studies also suggest that H&sub2;-antagonists might be effective in treating herpes viruses, such as shingles and herpes simplex [1].

Adverse drug reactions

H2 antagonists are generally well-tolerated, except for cimetidine where all of the following adverse drug reactions (ADRs) are common. Infrequent ADRs include hypotension. Rare ADRs include: headache, tiredness, dizziness, confusion, diarrhoea, constipation, and rash. (Rossi, 2005) Additionally, cimetidine may also cause gynecomastia in males, loss of libido, and impotence, which are reversible upon discontinuation.

Drug interactions

With regard to pharmacokinetics, cimetidine in particular interferes with some of the body's mechanisms of drug metabolism and elimination through the liver cytochrome P450 pathway. Specifically, cimetidine is an inhibitor of the P450 enzymes CYP1A2, CYP2C9,

CYP2C19, CYP2D6, CYP2E1, and CYP3A4. By reducing the metabolism of drugs through these enzymes, cimetidine may increase their serum concentrations to toxic levels. Examples of drugs affected include: warfarin, theophylline, phenytoin, lidocaine, quinidine, propranolol, labetalol, metoprolol, tricyclic antidepressants, some benzodiazepines, dihydropyridine calcium channel blockers, sulfonylureas, metronidazole, and some recreational drugs such as ethanol and MDMA.

Examples

Cimetidine was the prototypical member of the H***2*** antagonists. Further developments, using quantitative structure-activity relationships (QSAR) led to the development of further agents with improved tolerability-profiles. In the United States, all four members of the group are available over the counter in relatively low doses, and have become extremely popular medications marketed to heartburn sufferers.

- cimetidine (Tagamet)

ranitidine (Zantac)
famotidine (Pepcid)
nizatidine (Axid, Tazac)

Antihypertensive agents

Antihypertensives are a class of drugs that are used in medicine and pharmacology to treat hypertension (high blood pressure). There are many classes of antihypertensives, which—by varying means—act by lowering blood pressure. Evidence suggests that reduction of the blood pressure by 5-6 mmHg can decrease the risk of stroke by 40%, of coronary heart disease by 15-20%, and reduces the likelihood of dementia, heart failure, and mortality from cardiovascular disease.

Which type of medication to use initially for hypertension has been the subject of several large studies and resulting national guidelines.The fundamental goal of treatment should be the prevention of the important "endpoints" of hypertension such as heart attack, stroke and heart failure. Several classes of medications are effective in reducing blood pressure. However, these classes differ in side effect profiles, ability to prevent endpoints, and cost. The choice of more expensive agents, where cheaper ones would be equally effective, may have negative impacts on national healthcare budgets.[1]

In the United States, the JNC7 (The Seventh Report of the Joint National Committee on Prevention of Detection, Evaluation and Treatment of High Blood Pressure) recommends starting with a thiazide diuretic if single therapy is being initiated and another medication is not indicated.[2] This is based on a slightly better outcome for chlortalidone in the ALLHAT study versus other anti-hypertensives and because thiazide diuretics are relatively cheap.[3] A subsequent smaller study (ANBP2) published after the JNC7 did not show this small difference in outcome and actually showed a slightly better outcome for ACE-inhibitors in older male patients.[4]

Despite thiazides being cheap, effective, and recommended as the best first-line drug for hypertension by many experts, they are not prescribed as often as some newer drugs. Arguably, this is because they are off-patent and thus rarely promoted by the drug industry.[5]

In the United Kingdom, the June 2006 "Hypertension: management of hypertension in adults in primary care"[6] guideline of the National Institute for Health and Clinical Excellence, downgraded the role of beta-blockers due to their risk of provoking type 2 diabetes.[7]

Available drugs

Diuretics

Diuretics help the kidneys eliminate excess salt and water from the body's tissues and blood.

- Loop diuretics:
    - bumetanide
    ethacrynic acid

furosemide
torsemide

- Thiazide diuretics:
  - chlortalidone

epitizide
hydrochlorothiazide and chlorothiazide

- Thiazide-like diuretics:
  - indapamide

metolazone

- Potassium-sparing diuretics:
  - amiloride

triamterene

Although the above is a thorough list of diuretic agents, only the thiazide and thiazide-like diuretics have good evidence of beneficial effects on important endpoints of hypertension.

Antiadrenergics

Adrenergic receptor antagonists:

- Beta blockers**:**
  - atenolol

metoprolol
nadolol
oxprenolol
pindolol
propranolol
timolol

- Alpha blockers**:**
  - doxazosin

phentolamine
indoramin
phenoxybenzamine
prazosin
terazosin
tolazoline

- Mixed Alpha + Beta blockers:
  - bucindolol

carvedilol
labetalol

Although beta blockers lower blood pressure, they do not have as positive a benefit on endpoints as some other antihypertensives.[8] In particular, atenolol seems to be less useful

in hypertension than several other agents.[9] However, beta blockers have an important role in the prevention of heart attack in people who have already had a heart attack.[10]

Despite lowering blood pressure, alpha blockers have significantly poorer endpoint outcomes than other antihypertensives, and are no longer recommended as a first-line choice in the treatment of hypertension.[11] However, they may be useful for some men with symptoms of prostate disease.

Calcium channel blockers

Calcium channel blockers block the entry of calcium into muscle cells in artery walls.

- dihydropyridines:
  - amlodipine

felodipine
isradipine
nifedipine
nimodipine
nitrendipine

- non-dihydropyridines:
  - diltiazem

verapamil

ACE inhibitors

ACE inhibitors inhibit the activity of Angiotensin-converting enzyme (ACE), an enzyme responsible for the conversion of angiotensin I into angiotensin II, a potent vasoconstrictor.

- captopril

enalapril
fosinopril
lisinopril
perindopril
quinapril
ramipril
trandopril
benzapril

Angiotensin II receptor antagonists

Angiotensin II receptor antagonists work by antagonizing the activation of angiotensin receptors.

- candesartan

irbesartan
losartan
telmisartan
valsartan

Aldosterone antagonists

Aldosterone antagonists:

- spironolactone

Aldosterone antagonists are not recommended as first-line agents for blood pressure,[2] but spironolactone is useful in the treatment of heart failure.

Vasodilators

Vasodilators act directly on arteries to relax their walls so blood can move more easily through them; they are only used in medical emergencies.

- sodium nitroprusside

Centrally acting adrenergic drugs

Central alpha agonists lower blood pressure by stimulating alpha-receptors in the brain which open peripheral arteries easing blood flow. Central alpha agonists, like Clonidine, are usually prescribed when all other anti-hypertensive medications have failed.

- Clonidine

Guanabenz
Methyldopa

Adrenergic neuron blockers

- Guanethidine

Reserpine

Herbals provoking hypotension

- Agrimony

Celery
Cornsilk
Garlic
Ginger
Ginseng
Goldenseal
Hawthorn
Mistletoe
Nettle
Parsley
Pokeroot
Sage

Squill
Wild Carrot

Choice

The choice between the drugs is to a large degree determined by the characteristics of the patient being prescribed for, the drugs' side-effects, and cost. For example, asthmatics have been reported to have worsening symptoms when using beta blockers. Most drugs have other uses; sometimes the presence of other symptoms can warrant the use of one particular antihypertensive (such as beta blockers in case of tremor and nervousness, and alpha blockers in case of benign prostatic hyperplasia). The JNC 7 report outlines compelling reasons to choose one drug over the others for certain individual patients.[2]

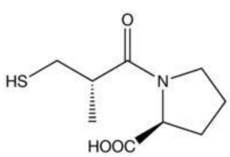
ACE inhibitors



Captopril, the first ACE inhibitor

ACE inhibitors, or inhibitors of *A*ngiotensin-*C*onverting *E*nzyme, are a group of pharmaceuticals that are used primarily in treatment of hypertension and congestive heart failure, in most cases as the drugs of first choice.

Clinical use

Indications for ACE inhibitors include:

- Prevention of cardiovascular disorders

Congestive heart failure
Hypertension
Left ventricular dysfunction
Prevention of nephropathy in diabetes mellitus

In several of these indications, ACE inhibitors are used first-line as several agents in the class have been clinically shown to be superior to other classes of drugs in the reduction of morbidity and mortality.

ACE inhibitors are often combined with diuretics in the control of hypertension (usually a thiazide), when an ACE inhibitor alone proves insufficient; and in chronic heart failure (usually furosemide) for improved symptomatic control. Thus there exists, on the market, combination products combining an ACE inhibitor with a thiazide (usually hydrochlorothiazide) in a single tablet to allow easy administration by patients.

Effects of ACE inhibitors

ACE inhibitors lower arteriolar resistance and increase venous capacitance; increase cardiac output and cardiac index, stroke work and volume, lower renovascular resistance, and lead to increased natriuresis (excretion of sodium in the urine).

Epidemiological and clinical studies have shown that ACE inhibitors reduce the progress of diabetic nephropathy independently from their blood pressure-lowering effect. This action of ACE inhibitors is utilised in the prevention of diabetic renal failure.

ACE inhibitors have been shown to be effective for indications other than hypertension even in patients with normal blood pressure. The use of a maximum dose of ACE inhibitors in such patients (including for prevention of diabetic nephropathy, congestive heart failure, prophylaxis of cardiovascular events) is justified because it improves clinical outcomes, independent of the blood pressure lowering effect of ACE inhibitors. Such therapy, of course, requires careful and gradual titration of the dose to prevent the patient suffering from the effects of rapidly decreasing their blood pressure (dizziness, fainting, etc).

Adverse effects

Common adverse drug reactions (e1% of patients) include: hypotension, cough, hyperkalemia, headache, dizziness, fatigue, nausea, renal impairment.[1]

A persistent dry cough is a relatively common adverse effect believed to be associated with the increases in bradykinin levels produced by ACE inhibitors, although the role of bradykinin in producing these symptoms remains disputed by some authors.[2] Patients who experience this cough are often switched to angiotensin II receptor antagonists.

Rash and taste disturbances, infrequent with most ACE inhibitors, are more prevalent in captopril and is attributed to its sulfhydryl moiety. This has led to decreased use of captopril in clinical setting, although it is still used in scintigraphy of the kidney.

Renal impairment is a significant adverse effect of all ACE inhibitors, and is associated with their effect on angiotensin II-mediated homeostatic functions such as renal bloodflow. ACE inhibitors can induce or exacerbate renal impairment in patients with renal artery stenosis. This is especially a problem if the patient is also concomitantly taking an NSAID and a diuretic - the so-called "triple whammy" effect - such patients are at very high risk of developing renal failure. [3]

Some patients develop angioedema due to increased bradykinin levels. There appears to be a genetic predisposition towards this adverse effect in patients who degrade bradykinin slower than average.[4]

Examples of ACE inhibitors

ACE inhibitors can be divided into three groups based on their molecular structure:

Sulfhydryl-containing ACE inhibitors

- Captopril (Capoten®), the first ACE inhibitor

Dicarboxylate-containing ACE inhibitors

This is the largest group, including:

- Enalapril (Vasotec®/Renitec®)

Ramipril (Altace®/Tritace®/Ramace®)
Quinapril (Accupril®)
Perindopril (Coversyl®)
Lisinopril (Lisodur®/Lopril®/Prinivil®/Zestril®)
Benazepril

Phosphonate-containing ACE inhibitors

- Fosinopril (Monopril®), the only member

Naturally occurring

Casokinins and lactokinins are breakdown products of casein and whey that occur naturally after ingestion of milk products, especially sour milk. Their role in blood pressure control is uncertain.[5]

Comparative information

Comparatively, all ACE inhibitors have similar antihypertensive efficacy when equivalent doses are administered. The main point-of-difference lies with captopril, the first ACE inhibitor, which has a shorter duration of action and increased incidence of certain adverse effects (cf. captopril).

Certain agents in the ACE inhibitor class have been proven, in large clinical studies, to reduce mortality post-myocardial infarction, prevent development of heart failure, etc. While these effects are likely to be class-effects, good evidence-based medicine practice would direct the use of those agents with established clinical efficacy.

Contraindications and precautions

The ACE inhibitors are contraindicated in patients with:

- Previous angioedema associated with ACE inhibitor therapy
Renal artery stenosis (bilateral, or unilateral with a solitary functioning kidney)

ACE inhibitors should be used with caution in patients with:

- Impaired renal function
Aortic valve stenosis or cardiac outflow obstruction
Hypovolaemia or dehydration
Haemodialysis with high flux polyacrylonitrile membranes

ACE inhibitors are ADEC Pregnancy category D, and should be avoided in women who are likely to become pregnant.[1] In the U.S., ACE inhibitors are required to be labelled with a "black box" warning concerning the risk of birth defects when taking during the second and third trimester. It has also been found that use of ACE inhibitors in the first trimester is also associated with a risk of major congenital malformations, particularly affecting the cardiovascular and central nervous systems.[6]

Potassium supplementation should be used with caution and under medical supervision owing to the hyperkalaemic effect of ACE inhibitors.

Angiotensin II receptor antagonists

ACE inhibitors share many common characteristics with another class of cardiovascular drugs called angiotensin II receptor antagonists, which are often used when patients are intolerant of the adverse effects produced by ACE inhibitors. ACE inhibitors do not completely prevent the formation of angiotensin II, as there are other conversion pathways, and so angiotensin II receptor antagonists may be useful because they act to prevent the action of angiotensin II at the AT***1*** receptor.

Use in combination with ACE inhibitors

While counterintuitive at first glance, the combination therapy of angiotensin II receptor antagonists with ACE inhibitors may be superior to either agent alone. This combination may increase levels of bradykinin while blocking the generation of angiotensin II and its activity at the AT***1*** receptor. This 'dual blockade' may be more effective than using an ACE inhibitor alone, because angiotensin II can be generated via non-ACE-dependent pathways. Preliminary studies suggest that this combination of pharmacologic agents may be advantageous in the treatment of essential hypertension, chronic heart failure, and nephropathy.[7][8] However, more studies are needed to confirm these highly preliminary results. While statistically significant results have been obtained for its role in treating hypertension, clinical significance may be lacking.[9]

Patients with heart failure may benefit from the combination in terms of reducing morbidity and ventricular remodeling.[10][11]

The most compelling evidence has been found for the treatment of nephropathy: this combination therapy partially reversed the proteinuria and also exhibited a renoprotective effect in patients afflicted with diabetic nephropathy, (Luno et al., 2005) and pediatric IgA nephropathy.[12]

History

The first step in the development of ACE inhibitors was the discovery of angiotensin converting enzyme (ACE) in 1956 by Leonard T. Skeggs. The importance of this enzyme in blood pressure regulation was initially underestimated. Fourteen years later, the pharmacologist Sérgio Henrique Ferreira discovered that the venom of the pit viper (Bothrops jararaca) was able to potentiate the action of bradykinin. A family of peptides, designated bradykinin potentiating factors (BPFs) was isolated from the venom and their action was linked to inhibition of bradykinin degradation by ACE.

The nonapeptide BPF teprotide (SQ 20,881) was found to have the greatest ACE inhibition potency and hypotensive effect in vivo. Teprotide had limited clinical value, however, due to its peptide nature and lack of activity when given orally. In the early 1970s, knowledge of the structure-activity relationship required for inhibition of ACE was growing. David Cushman, Miguel Ondetti and colleagues used peptide analogues to study the structure of ACE, using carboxypeptidase A as a model. Their discoveries led to the development of captopril, the first orally-active ACE inhibitor, in 1975.

Captopril was approved by the United States Food and Drug Administration in 1981. The first non-sulfhydryl-containing ACE inhibitor enalapril was marketed two years later. Since then, at least nine other ACE inhibitors have been marketed.

Alpha blockers

Alpha blockers (also called alpha-adrenergic blocking agents) constitute a variety of drugs which block ±1-adrenergic receptors in arteries and smooth muscles.

Indications

These drugs may be used to treat:

- benign prostatic hyperplasia (BPH)
high blood pressure (hypertension). This is not typically the drug of choice unless the patient also has BPH.
symptoms of non inflammatory chronic pelvic pain syndrome, a type of prostatitis. As a side effect they may reduce blood pressure and result in lightheadedness.

Examples of alpha blockers

Alpha blockers include:

- Doxazosin (Cardura)
Prazosin (Minipress)
Phenoxybenzamine
Phentolamine (Rogitine)
Tamsulosin (Flomaxtra/Flomax)
Alfuzosin (Uroxatral)
Terazosin (Hytrin)

Tamsulosin is relatively selective for ±***1a***-adrenergic receptors, which are mainly present in the prostate. Hence, it may have a more selective action in BPH with minimal effects on blood pressure.

Adverse effects and interactions

By reducing ±***1***-adrenergic activity of the blood vessels, these drugs may cause hypotension and interrupt the baroreflex response. In doing so, they may cause dizziness, lightheadedness, or fainting when rising from a lying or sitting posture (known as orthostatic hypotension or postural hypotension). For this reason, it is generally recommended that alpha blockers should be taken at bedtime. Additionally, the risk of orthostatic hypotension may be reduced by starting at a low dose and titrating upwards as needed.

Because these medications may cause orthostatic hypotension, as well as hypotension in general, these agents may interact with other medications that increase risk for hypotension, such as other antihypertensives and vasodilators.

As discussed above, tamsulosin may have less risk for hypotension and orthostatic hypotension due to its selectivity for ±***1a***-adrenergic receptors. On the other hand, (a) shows an elevated risk for floppy iris syndrome, and (b) mighgt show ADRs characteristic of the sulfa related drugs.

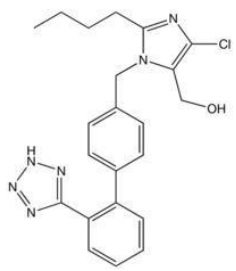
Angiotensin II receptor antagonist



Losartan, the first ARB

Angiotensin II receptor antagonists, also known as *angiotensin receptor blockers* (ARBs), *AT*1*-receptor antagonists* or *sartans*, are a group of pharmaceuticals which modulate the renin-angiotensin-aldosterone system. Their main use is in hypertension (high blood pressure), diabetic nephropathy (kidney damage due to diabetes) and congestive heart failure.

Mode of action

These substances are AT***1***-receptor antagonists – that is, they block the activation of angiotensin II AT1 receptors. Blockade of AT***1*** receptors directly causes vasodilation, reduces secretion of vasopressin, reduces production and secretion of aldosterone, amongst other actions – the combined effect of which is reduction of blood pressure.

Uses

Angiotensin II receptor antagonists are primarily used for the treatment of hypertension where the patient is intolerant of ACE inhibitor therapy. They do not inhibit the breakdown of bradykinin or other kinins, and are thus only rarely associated with the persistent dry cough that commonly limits ACE inhibitor therapy. More recently, they have been used for the treatment of heart failure in patients intolerant of ACE inhibitor therapy, particularly candesartan. Irbesartan and losartan have trial data showing benefit in hypertensive patients with type II diabetes, and may delay the progression of diabetic nephropathy.

Adverse effects

This class of drugs is usually well-tolerated, with common adverse drug reactions (ADRs) including: dizziness, headache, and/or hyperkalaemia. Infrequent ADRs associated with therapy include: first dose orthostatic hypotension, rash, diarrhoea, dyspepsia, abnormal liver function, muscle cramp, myalgia, back pain, insomnia, decreased haemoglobin levels, renal impairment, pharyngitis, and/or nasal congestion. (Rossi, 2006)

While one of the main rationales for the use of this class is the avoidance of dry cough associated with ACE inhibitor therapy, it may still rarely occur. Additionally, there is also a small risk of cross-reactivity in patients who have experienced angioedema with ACE inhibitor therapy. (Rossi, 2006)

Diuretics

A *diuretic* (colloquially called a water pill) is any drug or herb that elevates the rate of bodily urine excretion (diuresis). Diuretics also decrease the extracellular fluid (ECF) volume, and are primarily used to produce a negative extracellular fluid balance. Caffeine, cranberry juice and alcohol are all weak diuretics.

Uses

In medicine, diuretics are used to treat heart failure, liver cirrhosis, hypertension and certain kidney diseases. Diuretics alleviate the symptoms of these diseases by causing sodium and water loss through the urine. As urine is produced by the kidney, sodium and water – which cause edema related to the disease – move into the blood to replace the volume lost as urine, thereby reducing the pathological edema. Some diuretics, such as acetazolamide, help to make the urine more alkaline and are helpful in increasing excretion of substances such as aspirin in cases of overdose or poisoning.

The antihypertensive actions of some diuretics (thiazides and loop diuretics in particular) are independent of their diuretic effect. That is, the reduction in blood pressure is not due to decreased blood volume resulting from increased urine production, but occurs through other mechanisms and at lower doses than that required to produce diuresis. Indapamide was specifically designed with this is mind, and has a larger therapeutic window for hypertension (without pronounced diuresis) than most other diuretics.

Mechanism of action

Classification of common diuretics and their mechanisms of action

Agent Group = Examples = Mechanism

- = Ethanol, Water = inhibits vasopressin secretion

Acidifying salts = $CaCl_2$, NH_4Cl

Arginine vasopressin receptor 2 antagonists = amphotericin B, lithium citrate = inhibit vasopressin's action on nephron's collecting duct

Carbonic anhydrase inhibitors = acetazolamide, dorzolamide = inhibit H^+ secretion, resultant promotion of Na^+ and K^+ excretion

Loop diuretics = bumetanide, ethacrynic acid, furosemide, torsemide = inhibit the cotransporter in the medullary thick ascending limb of the loop of Henle

Osmotic diuretics = glucose, mannitol = promote osmotic diuresis

Potassium-sparing diuretics = amiloride, spironolactone, triamterene = inhibition within collecting ducts of Na^+-K^+ exchange: Spironolactone inhibits aldosterone action, Amiloride inhibits epithelial sodium channels

Thiazides = bendroflumethiazide, hydrochlorothiazide = inhibit Na^+/Cl^- reabsorption from nephrons' distal convoluted tubules

Xanthines = caffeine, theophylline = inhibit tubular reabsorption of Na^+, increase glomerular filtration rate

Chemically, diuretics are a diverse group of compounds that either stimulate or inhibit various hormones that naturally occur in the body to regulate urine production by the kidneys.

Alcohol produces diuresis through modulation of the vasopressin system.

Aldosterone

Aldosterone is a steroid hormone produced by the outer-section (zona glomerulosa) of the adrenal cortex in the adrenal gland to regulate sodium and potassium balance in the blood. It is synthesized from cholesterol by aldosterone synthase, which is absent in other sections of the adrenal gland. It is the sole endogenous member of the class of mineralocorticoids. Acting on mineralocorticoid receptors (MR) on principal cells in the distal tubule of the kidney nephron, it increases the permeability of their apical (luminal)

membrane to potassium and sodium and activates their basolateral Na+/K+ pumps, stimulating ATP hydrolysis, reabsorbing sodium (Na+) ions and water into the blood, and excreting potassium (K+) ions into the urine. Aldosterone also stimulates H+ secretion by ±-intercalated cells in the collecting duct, regulating plasma bicarbonate (HCO3) levels and its acid/base balance.[1]

Aldosterone is responsible for the reabsorption of about 2% of filtered sodium in the kidneys, which is nearly equal to the entire sodium content in human blood under normal GFR (glomerular filtration rate).[2]

Unlike neuroreceptors, classic steroid receptors are intracellularly located. The aldosterone/MR receptor complex binds on the DNA to the hormone response element, which alters protein synthesis and the transcription of messenger RNA. Some of the transcribed genes are important for transepithelial sodium transport, including serum and glucocorticoid-induced kinase, channel-inducing factor, K-ras2A, and three subunits of the epithelial sodium channel.

Aldosterone synthesis is stimulated by increased plasma angiotensin II or potassium levels, which are present in proportion to plasma sodium deficiencies. It is also stimulated by plasma acidosis. The secretion of aldosterone has a diurnal rhythm; about 75% of the daily production is secreted between 04:00 am and 10:00 am each day.[3]

Aldesterone release is also stimulated by the stretch receptors located in the atria of the heart. If decreased blood pressure is detected, the adrenal gland is stimulated by these stretch receptors to release aldesterone, which increases sodium reabsorption from the urine, sweat and the gut. This causes increased osmolarity in the extracellular fluid which will eventually return blood pressure toward normal.

Aldosterone and the kidney

Control of aldosterone release

- The role of the renin-angiotensin system

The role of sympathetic nerves
The role of baroreceptors
The role of the juxtaglomerular apparatus
The plasma concentration of potassium

Loop diuretics

Loop diuretics are diuretics that act on the ascending loop of Henle in the kidney. They are primarily used in medicine to treat hypertension and edema often due to congestive heart failure or renal insufficiency.

Mechanism of action

Loop diuretics act on the Na-K-2Cl symporter in the thick ascending limb of the loop of Henle to inhibit sodium and chloride reabsorption. Because magnesium and calcium reabsorption in the thick ascending limb is dependent on sodium and chloride concentrations, loop diuretics also inhibit their reabsorption. By disrupting the reabsorption of these ions, loop diuretics prevent the urine from becoming dilute and disrupt the generation of a hypertonic renal medulla. Without such a concentrated medulla, water has less of an osmotic driving force to leave the collecting duct system, ultimately resulting in increased urine production. This diuresis leaves less water to be reabsorbed into the blood, resulting in a decrease in blood volume.

Loop diuretics also cause vasodilation of the veins and of the kidney's blood vessels, mechanically causing a decrease in blood pressure.

The collective effects of decreased blood volume and vasodilation decrease blood pressure and ameliorate edema.

Clinical use

Loop diuretics are principally used in the following indications (Rossi, 2004):

- edema associated with heart failure, hepatic cirrhosis, renal impairment, nephrotic syndrome
- hypertension
- adjunct in cerebral/pulmonary edema where rapid diuresis is required (IV injection)

They are also sometimes used in the management of severe hypercalcemia in combination with adequate rehydration (Rossi, 2004).

Loop diuretic resistance

Renal insufficiency causes decreased bloodflow to the kidneys, which decreases the glomerular filtration rate (GFR) and reduces the ability of loop diuretics to reach their target organ, the loop of Henle. Similarly, non-steroidal anti-inflammatory drugs also decrease GFR with comparable results. In patients with reduced GFR, ceiling dosages of loop diuretics are increased proportional to the decrease in GFR. Simultaneous treatment with a thiazide diuretic such as hydrochlorothiazide (to inhibit sodium reabsorption at multiple sites in the nephron) is often successful.

Patients with congestive heart failure tend to retain sodium, also necessitating an increase in dosage. The same is true for patients with increased sodium intake.

Adverse effects

The most common adverse drug reactions (ADRs) are dose-related and relate to the effect of loop diuretics on diuresis and electrolyte balance.

Common ADRs include: hyponatremia, hypokalemia, hypomagnesemia, dehydration, hyperuricemia, gout, dizziness, postural hypotension, syncope (Rossi, 2004).

Infrequent ADRs include: dyslipidemia, increased serum creatinine concentration, hypocalcemia, rash (Rossi, 2004).

Ototoxicity (damage to the ear) is a serious, but rare ADR associated with use of loop diuretics. This may be limited to tinnitus and vertigo, but may result in deafness in serious cases.

Loop diuretics may also precipitate renal failure in patients concomitantly taking an NSAID and an ACE inhibitor -- the so-called "triple whammy" effect (Thomas, 2000).

Examples of loop diuretics

- Furosemide
- Bumetanide
- Ethacrynic acid
- Torasemide

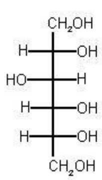
Osmotic diuretics - Sorbitol



Chemical name Sorbitol

E number E 420

Chemical formula $C_6H_{14}O_6$

Molecular mass 182.17 g/mol

Melting point 95 °C

Boiling point 296 °C

Density 0.68 g/cm^3

CAS number [50-70-4]

SMILES OCC(O)C(O)C(O)C(O)CO

IUPAC name hexane-1,2,3,4,5,6-hexaol

Sorbitol, also known as *glucitol*, is a sugar alcohol the body metabolises slowly. It is obtained by reduction of glucose changing the aldehyde group to an additional hydroxyl group hence the name sugar alcohol.

Sorbitol is used in various cough syrups, and is usually listed under the inactive ingredients. There is a growing opinion within the medical community that it should be listed as an active ingredient, because too much Sorbitol (about 50g or more for adults) can cause severe gastro-intestinal problems.

Sorbitol is a sugar substitute often used in diet foods (including diet drinks) and sugar-free chewing gum. It also occurs naturally in many stone fruits. Sorbitol is also referred to as a nutritive sweetener because it provides calories or energy to the diet - 2.6 calories (11 kilojoules) per gram versus the average 4 calories (17 kJ) of sugar and starch, while retaining 60% of the sweetness.

Sorbitol is produced naturally by the body, yet sorbitol is poorly digested by the body. Too much sorbitol in cells can cause damage.

Diabetic retinopathy and neuropathy may be related to excess sorbitol in the cells of the eyes and nerves. The source of this sorbitol in diabetics is excess glucose, which goes through the polyol pathway. Ingesting large amounts of sorbitol can lead to some abdominal pain, gas, and mild to severe diarrhea. Sorbitol can also aggravate irritable bowel syndrome and fructose malabsorption.

Sorbitol is often used in modern cosmetics as a humectant and thickener. Some transparent gels can only be made with sorbitol as it has a refractive index sufficiently high for transparent formulations. It is also used as a humectant in some cigarettes.

Sorbitol is used as a cryoprotectant additive (mixed with sucrose and sodium polyphosphates) in the manufacture of surimi, a highly refined, uncooked fish paste most commonly produced from Alaska (or walleye) pollock (Theragra chalcogramma).

Sorbitol is identified as a potential key chemical intermediate [1] from biomass resources. Complete reduction of sorbitol opens the way to alkanes such as hexane which can be used as a biofuel. Sorbitol itself provides much of the hydrogen required for the transformation.

$19\ C_6O_6H_{14}$ ’ $13\ C_6H_{14} + 36\ CO_2 + 42\ H_2O$

The above chemical reaction is exothermic and 1.5 mole of sorbitol generates 1 mole of hexane. When hydrogen is co-fed no carbon dioxide production takes place.

Potassium-sparing diuretics

Potassium-sparing diuretic refers to diuretic drugs that do not promote the secretion of potassium into the urine. They are used as adjunctive therapy, together with other drugs, in the treatment of hypertension and management of congestive heart failure.

Potassium-sparing diuretics do not share any obvious chemical similarities, except for the steroid-structure of the aldosterone antagonists. Those in clinical use include:

- Amiloride
- Triamterene
- Aldosterone antagonists
  - Spironolactone
  - Eplerenone

Thiazides

Thiazides are diuretics, a class of drug that promote water loss from the body. They inhibit Na+/Cl- reabsorption from the distal convoluted tubules in the kidneys. Thiazides also cause loss of potassium and an increase in serum uric acid. The chemical structure of the original thiazide diuretics contained a thiazide ring system; the term is also used for drugs with a similar action that are not chemically thiazides, such as chlortalidone and metolazone.

Thiazides are often used to treat hypertension. They are the recommended first-line treatment in the US (JNC VII) guidelines and a recommended treatment in the European (ESC/ESH) guidelines. They have been shown to prevent hypertension-related morbidity and mortality although the mechanism is not fully understood. They may cause vasodilation

by desensitizing the vascular smooth muscle cells to calcium release induced by norepinephrine (PMID 15611360).

Side effects can include hypokalemia, increased serum cholesterol, and impotence. The side effect of hypokalemia has motivated combining thiazides with ACE inhibitors, which also lower blood pressure but cause hyperkalemia as a side effect. Long-term usage of thiazides is also linked to increased levels of homocysteine, a toxic amino acid byproduct, has been associated with atherosclerosis. It is recommended that patients receiving long-term thiazide treaments also receive folic acid supplements to combat the risk.

Thiazides also lower urinary calcium excretion. That is why they are used to prevent calcium-containing kidney stones. This effect is associated with positive calcium balance and is associated with an increase in bone mineral density and reductions in fracture rates attributable to osteoporosis.

Thiazide treatment may be combined with ACE inhibitors to increase diuresis without changing plasma potassium concentrations. While ACE inhibitors cause diuresis with potassium retention, thiazide increases potassium excretion. Their combined effects on potassium cancel each other out.

It should be noted that thiazides pass through breast milk, and in some cases, decrease the flow of breast milk. There is no specific information regarding the use of thiazides in children, but it is still advised that mothers avoid using thiazides during the first month of breast feeding.

Mechanism of hypokalemia

Thiazide-induced hypokalemia (decreased plasma potassium concentration) is partly caused by the direct inhibition of the thiazide-sensitive NaCl transporter in the distal convoluted tubule, and also as a result of activation of the renin-angiotensin system. Decreased sodium reabsorption decreases the sodium gradient the nephron usually uses to reabsorb potassium, resulting in greater potassium excretion. In addition, the increased flow of tubular fluid increases the potassium gradient between the epithelium and lumen, driving the secretion of potassium. Finally, low blood volume induced by diuresis results in activation of the renin-angiotensin system, activating aldosterone, which significantly elevates the secretion of potassium. For this reason, ACE inhibitors, which inhibit angiotensin II production and therefore aldosterone activation, are frequently used in combination with thiazides to combat hypokalemia.

Antimicrobials

An *antimicrobial* is a substance that kills or inhibits the growth of microbes such as bacteria (antibacterial activity), fungi (antifungal activity), viruses (antiviral activity), or parasites (anti-parasitic activity).

Main classes

Antibiotics

Antibiotics are generally used to treat bacterial infections. The toxicity to humans and other animals from antibiotics are generally considered to be low. However, prolonged use of certain antibiotics can decrease the number of gut flora, which can have a negative impact on health. Some recommend that during or after prolonged antibiotic use, that one should consume probiotics and eat reasonably to replace destroyed gut flora.

The term antibiotic originally described only those formulations derived from living organisms but is now applied also to synthetic antimicrobials, such as the sulfonamides.

The discovery, development, and clinical use of antibiotics during the 20th century have substantially decreased the morbidity and mortality from bacterial infections. The antibiotic era began with the therapeutic application of sulfonamide drugs in 1936, followed by a "golden" period of discovery from approximately 1945 to 1970, when a number of structurally diverse, highly effective agents were discovered and developed. However, since 1980 the introduction of new antimicrobial agents for clinical use has declined. Paralleled to this there has been an alarming increase in bacterial resistance to existing agents.[1] Antibiotics are among the most commonly used drugs. For example, 30% or more hospitalized patients are treated with one or more courses of antibiotic therapy. However, antibiotics are also among the drugs commonly misused by physicians, e.g. usage of antibiotic agents in viral respiratory tract infection. The inevitable consequence of widespread and injudicious use of antibiotics has been the emergence of antibiotic-resistant pathogens, resulting in the emergence of a serious threat to global public health. The resistance problem demands that a renewed effort be made to seek antibacterial agents effective against pathogenic bacteria resistant to current antibiotics. One of the possible strategies towards this objective is the rational localization of bioactive phytochemicals.

Traditional healers have long used plants to prevent or cure infectious disease. Many of these plants have been investigated scientifically for antimicrobial activity and a large number of plant products have been shown to inhibit the growth of pathogenic microorganisms. A number of these agents appear to have structures and modes of action that are distinct from those of the antibiotics in current use, suggesting that cross-resistance with agents already in use may be minimal. So, it is worthwhile to study plants and plant products for activity against resistant bacteria.

Essential oils

Many essential oils are included in pharmacopoeias as having antimicrobial activity, including:

- Oregano oil - in alternative medicine
Tea tree oil - in cosmetics, medicine
Mint oil - in medicine, cosmetics (tooth paste etc.)
Sandalwood oil - in cosmetics
Clove oil - stomatology etc.
Nigella sativa (Black cumin) oil
Onion oil (Allium cepe) - phytoncides, in phytotherapy
Leleshwa oil
Lavender oil
Lemon oil

- Eucalyptus **oil**

- Peppermint **oil**

- Cinnamon oil
Clove oil

Cations and elements

Many heavy metal cations such as Hg^{2+}, Cu^{2+}, and Pb^{2+} have antimicrobial activities, but are also very toxic to other living organisms, thus making them unsuitable for treating infectious diseases.

Ionic Silver is an excellent antimicrobial, with relatively low toxicity against non-target organisms. However, prolonged high intake of ionic silver may lead to health problems, such as argyria. In an inorganic matrix, silver ions are slowly released via an ion-exchange mechanism. The release of silver ions from the surface is slow, but just fast enough to maintain an effective concentration at and near the surface of the material. Once the silver ion leaves the surface of the matrix and reaches the surface of the microorganism, its mechanism of antimicrobial action begins. Uptake of silver ions by a microbial cell can occur by several mechanisms, including passive diffusion and active transport by systems that normally transport essential ions.

While the silver ions may bind non-specifically to cell surfaces and cause disruptions in cellular membrane function, it is widely believed that the antimicrobial properties of silver depend upon silver binding within the cell. Once inside the cell, silver ions begin to interrupt critical functions of the microorganism. Silver ions are highly reactive and readily bind to electron donor groups containing sulphur, oxygen and nitrogen, as well as negatively charged groups such as phosphates and chlorides. A prime molecular target for the silver ion resides in cellular thiol (-SH) groups, commonly found in critical proteins called enzymes. Enzymes become denatured because of conformational changes in the molecule that result

from silver ion binding. Many of the enzymes that silver ions denature are necessary in the cellular generation of energy.

If the energy source of the cell is incapacitated, the cell cannot maintain osmotic pressure, necessary substrates leak out of the cell and the microbe will quickly die. In addition to the well-known reaction of silver ions and proteins, several studies suggest that silver ions react with the base pairs of DNA, interfering with DNA replication. Studies on silver nanoparticles have shown antimicrobial activity, including activity against pathogenic Escherichia coli and HIV.

Antibiotics

An *antibiotic* is a drug that kills or slows the growth of bacteria. They have no effect against viruses, fungi, or parasites. Antibiotics are one class of antimicrobials, a larger group which also includes anti-viral, anti-fungal, and anti-parasitic drugs. They are relatively harmless to the host, and therefore can be used to treat infections. The term, coined by Selman Waksman, originally described only those formulations derived from living organisms, in contrast to "chemotherapeutic agents", which are purely synthetic. Nowadays the term "antibiotic" is also applied to synthetic antimicrobials, such as the sulfa drugs. Antibiotics are generally small molecules with a molecular weight less than 2000. They are not enzymes. Some antibiotics have been derived from mold, for example the penicillin class.

Unlike previous treatments for infections, which included poisons such as strychnine and arsenic, antibiotics were labelled "magic bullets": drugs which targeted disease without harming the host. Conventional antibiotics are not effective in viral, fungal and other nonbacterial infections, and individual antibiotics vary widely in their effectiveness on various types of bacteria. Antibiotics can be categorised based on their target specificity: 'narrow-spectrum' antibiotics target particular types of bacteria, such as Gram-negative or Gram-positive bacteria, while 'wide-spectrum' antibiotics affect a larger range of bacteria.

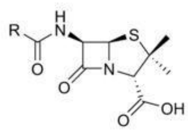
The effectiveness of individual antibiotics varies with the location of the infection, the ability of the antibiotic to reach the site of infection, and the ability of the bacteria to resist or inactivate the antibiotic. Some antibiotics actually kill the bacteria (bactericidal), whereas others merely prevent the bacteria from multiplying (bacteriostatic) so that the host's immune system can overcome them.

Oral antibiotics are the simplest approach when effective, with intravenous antibiotics reserved for more serious cases. Antibiotics may sometimes be administered topically, as with eyedrops or ointments.

Antibiotics can also be classified by the organisms against which they are effective, and by the type of infection in which they are useful, which depends on the sensitivities of the

organisms that most commonly cause the infection and the concentration of antibiotic obtainable in the affected tissue.

History



Penicillin

Many ancient cultures, including the ancient Egyptians, ancient Greeks and ancient Chinese, already used moulds and plants to treat infections. This worked because some moulds produce antibiotic substances. However, they couldn't distinguish or distil the active component in the moulds.

Modern research on antibiotics began in Britain with the discovery of Penicillin in 1928 by Alexander Fleming. More than ten years later, Ernst Chain and Howard Florey became interested in his work, and came up with the purified form of penicillin. The three shared the 1945 Nobel Prize in Medicine. "Antibiotic" was originally used to refer only to substances extracted from a fungus or other microorganism, but has come to include also the many synthetic and semi-synthetic drugs that have antibacterial effects.

Classes of antibiotics

At the highest level, antibiotics can be classified as either bactericidal or bacteriostatic. Bactericidals kill bacteria directly where bacteriostatics prevent them dividing. However, these classifications are based on laboratory behaviour; in practice, both of these will end a bacterial infection.

Antibiotics[1]

Class: **Aminoglycosides**

Infections caused by Gram-negative bacteria, such as Escherichia coli and Klebsiella. Side Effects: Hearing loss, Vertigo, Kidney damage

- Amikacin (Amikin)
- Gentamicin (Garamycin)
- Kanamycin
- Neomycin
- Netilmicin
- Streptomycin
- Tobramycin (Nebcin)

Class: Carbacephem

- Loracarbef (Lorabid)

Class: Carbapenems

- Ertapenem
- Imipenem/Cilastatin (Primaxin)
- Meropenem

Class: Cephalosporins (First generation)

Side Effects: Gastrointestinal upset and diarrhea. Nausea (if alcohol taken concurrently). Allergic reactions

- Cefadroxil (Duricef)
- Cefazolin (Ancef)
- Cephalexin (Keflex)

Class: Cephalosporins (Second generation)

Side Effects: Gastrointestinal upset and diarrhea. Nausea (if alcohol taken concurrently). Allergic reactions

- Cefaclor (Ceclor)
- Cefamandole (Mandole)
- Cefoxitin
- Cefprozil (Cefzil)
- Cefuroxime (Ceftin)

Class: Cephalosporins (Third generation)

Side Effects: Gastrointestinal upset and diarrhea. Nausea (if alcohol taken concurrently). Allergic reactions

- Cefixime
- Cefdinir (Omnicef)
- Cefditoren
- Cefoperazone (Cefobid)
- Cefotaxime (Claforan)
- Cefpodoxime
- Ceftazidime (Fortum)
- Ceftibuten
- Ceftizoxime
- Ceftriaxone (Rocephin)

Class: Cephalosporins (Fourth generation)

Side Effects: Gastrointestinal upset and diarrhea. Nausea (if alcohol taken concurrently). Allergic reactions

- Cefepime (Maxipime)

Class: **Glycopeptides**

- Teicoplanin
- Vancomycin (Vancocin)

Class: **Macrolides**

Streptococcal infections, syphilis, respiratory infections, mycoplasmal infections, Lyme disease. Side Effects: Nausea, vomiting, and diarrhea (especially at higher doses). Jaundice

- Azithromycin (Zithromax, Sumamed)
- Clarithromycin **(Biaxin)**
- Dirithromycin
- Erythromycin
- Roxithromycin
- Troleandomycin

Class: Monobactam

- Aztreonam

Class: **Penicillins**

Wide range of infections; penicillin used for streptococcal infections, syphilis, and Lyme disease. Side Effects: Gastrointestinal upset and diarrhea. Allergy with serious anaphylactic reactions. Brain and kidney damage (rare).

- Amoxicillin **(Novamox)**
- Ampicillin
- Azlocillin
- Carbenicillin
- Cloxacillin
- Dicloxacillin

    - Flucloxacillin
    - Mezlocillin
    - Nafcillin

- Penicillin

    - Piperacillin
    - Ticarcillin

Class: Polypeptides

Eye, ear or bladder infections; usually applied directly to the eye or inhaled into the lungs; rarely given by injection. Side Effects: Kidney and nerve damage (when given by injection).

- Bacitracin (Mupirocin)
- Colistin
- Polymyxin B

Class: **Quinolones**

Urinary tract infections, bacterial prostatitis, bacterial diarrhea, gonorrhea. Side Effects: Nausea (rare)

- Ciprofloxacin (Ciproxin, Ciplox)
- Enoxacin
- Gatifloxacin (Tequin)
- Levofloxacin (Levaquin)
- Lomefloxacin
- Moxifloxacin (Avelox)
- Norfloxacin
- Ofloxacin (Ocuflox)
- Trovafloxacin (Trovan)

Class: **Sulfonamides**

Urinary tract infections (except sulfacetamide and mafenide); mafenide is used topically for burns. Side Effects: Nausea, vomiting, and diarrhea. Allergy (including skin rashes). Crystals in urine. Kidney failure. Decrease in white blood cell count. Sensitivity to sunlight

- Mafenide
- Prontosil (archaic)
- Sulfacetamide
- Sulfamethizole
- Sulfanilimide (archaic)
- Sulfasalazine

- Sulfisoxazole
- Trimethoprim
- Trimethoprim-Sulfamethoxazole (Co-trimoxazole) (TMP-SMX) (Bactrim)

Class: **Tetracyclines**

Syphilis, chlamydial infections, Lyme disease, mycoplasmal infections, acne rickettsial infections. Side Effects: Gastrointestinal upset. Sensitivity to sunlight. Staining of teeth. Potential toxicity to mother and fetus during pregnancy

- Demeclocycline
- Doxycycline (Vibramycin)
- Minocycline
- Oxytetracycline

- Tetracycline **(Sumycin)**

Class: Others

- Chloramphenicol (Chloromycetin)
- Clindamycin (Cleocin)
- Ethambutol
- Fosfomycin
- Furazolidone
- Isoniazid
- Linezolid (Zyvox)
- Metronidazole (Flagyl)
- Nitrofurantoin (Macrodantin)
- Platensimycin
- Pyrazinamide
- Quinupristin/Dalfopristin (Syncercide)
- Rifampin
- Spectinomycin

Production

Since the first pioneering efforts of Florey and Chain in 1939, the importance of antibiotics to medicine has led to much research into discovering and producing them. The process of production usually involves screening of wide ranges of microorganisms, testing and modification. Production is carried out using fermentation; a process that is important in anaerobic conditions when there is no oxidative phosphorylation to maintain the production of ATP (Adenosine triphosphate) by glycolysis.

Side effects

Possible side effects are varied, and range from fever and nausea to major allergic reactions. One of the more common side effects is diarrhea, which results from the antibiotic disrupting the normal balance of intestinal flora, (which some people believe may be re-

balanced by taking probiotics). Other side effects can result from interaction with other drugs, such as elevated risk of tendon damage from administration of a quinolone antibiotic with a systemic corticosteroid.

It is a common assertion that some antibiotics can interfere with the efficiency of birth control pills. Although there remain few known cases of complication, the majority of antibiotics do not interfere with oral contraception, despite widespread misinformation to the contrary.[2]

Antibiotic misuse

Common forms of antibiotic misuse include failure to take the entire prescribed course of the antibiotic, usually because the patient feels better, but before the infecting organism is completely eradicated. In addition to treatment failure, these practices can result in antibiotic resistance in which the bacteria survive the abbreviated treatment. Taking antibiotics in inappropriate situations is another common form of antibiotic misuse. Common examples of this would be the use of antibacterials for viral infections such as the common cold.

In the United States, vast quantities of certain antibiotics are routinely included as low doses in the diet of some kinds of healthy farm animals, where this practice has been shown to make animals grow faster. Opponents of this practice, however, point out the likelihood that it also leads to an environment conducive to the evolution of antibiotic resistance, frequently in bacteria that are known to also infect humans. There has been no convincing evidence yet that the evolution of antibiotic resistance in such bacteria is actually occurring. As the majority of bacteria is killed in the pasteurization process applied to the milk, and the cooking of the meat, of such animals, any possible resistance may go unnoticed until the bacteria survives it. Theoretically, though, there is a significant possibility that such resistances could be transferred through bacterial plasmids, and the aforementioned conditions of continuous, low-dose antibiotics are ideal for the development of antibiotic resistance.

Excessive use of prophylactic antibiotics in travelers may also be classified as misuse.

Antibiotic resistance

Main article: Antibiotic resistance

Use or misuse of antibiotics may result in the development of antibiotic resistance by the infecting organisms, similar to the development of pesticide resistance in insects. Evolutionary theory of genetic selection requires that as close as possible to 100% of the infecting organisms be killed off to avoid selection of resistance; if a small subset of the population survives the treatment and is allowed to multiply, the average susceptibility of this new population to the compound will be much less than that of the original population, since they have descended from those few organisms which survived the original treatment. This survival often results from an inheritable resistance to the compound which was infrequent in the original population but is now much more frequent in the descendants thus selected entirely from those originally infrequent resistant organisms.

Antibiotic resistance has become a serious problem in both the developed and underdeveloped nations. By 1984 half of the people with active tuberculosis in the United States had a strain that resisted at least one antibiotic. In certain settings, such as hospitals and some child-care locations, the rate of antibiotic resistance is so high that the normal, low cost antibiotics are virtually useless for treatment of frequently seen infections. This leads to more frequent use of newer and more expensive compounds, which in turn leads inexorably to the rise of resistance to those drugs, and a never-ending ever-spiraling race to discover new and different antibiotics ensues, just to keep us from losing ground in the battle against infection. The fear is that we will eventually fail to keep up in this race, and the time when people did not fear life-threatening bacterial infections will be just a memory of a golden era.

Another example of selection is Staphylococcus aureus, which could be treated successfully with penicillin in the 1940s and 1950s. At present, nearly all strains are resistant to penicillin, and many are resistant to nafcillin, leaving only a narrow selection of drugs such as vancomycin useful for treatment. The situation is worsened by the fact that genes coding for antibiotic resistance can be transferred between bacteria, making it possible for bacteria never exposed to an antibiotic to acquire resistance from those which have. The problem of antibiotic resistance is worsened when antibiotics are used to treat disorders in which they have no efficacy, such as the common cold or other viral complaints, and when they are used widely as prophylaxis rather than treatment (as in, for example, animal feeds), because this exposes more bacteria to selection for resistance.

Beyond antibiotics

Unfortunately, the comparative ease of finding compounds which safely cured bacterial infections proved much harder to duplicate with respect to fungal and viral infections. Antibiotic research led to great strides in our knowledge of basic biochemistry and to the current biological revolution; but in the process it was discovered that the susceptibility of bacteria to many compounds which are safe to humans is based upon significant differences between the cellular and molecular physiology of the bacterial cell and that of the mammalian cell. In contrast, despite the seemingly huge differences between fungi and humans, the basic biochemistries of the fungal cell and the mammalian cell are much more similar; so much so that there are few therapeutic opportunities for compounds to attack a fungal cell which will not harm a human cell. Similarly, we know now that viruses represent an incredibly minimal intracellular parasite, being stripped down to a few genes worth of DNA or RNA and the minimal molecular equipment needed to enter a cell and actually take over the machinery of the cell to produce new viruses. Thus, the great bulk of viral metabolic biochemistry is not merely similar to human biochemistry, it actually is human biochemistry, and the possible targets of antiviral compounds are restricted to the relatively very few components of the actual virus itself.

Research into bacteriophages is ongoing at the moment. Bacteriophages are a specific type of virus that only targets bacteria. Research suggests that nature has evolved several types of bacteriophage for each type of bacteria. While research into bacteriophages is only in its infancy the results are promising and have already lead to major advances in microscopic imaging.[3] While bacteriophages provide a possible solution to the problem of

antibacterial resistance there is as of yet no proof that we will actually be able to deploy these microscopic killers in humans, we can only continue the research and see where it leads.

Phage therapy has been used in the past on humans in the US and Europe during the 1920s and 1930s, however due to not fully understanding the mechanism by which phage therapy worked, these treatments had mixed results. With the discovery of penicillin in the 1940s, Europe and the US changed to using antibiotics. However, in the former Soviet Union phage therapies continued to be studied. In the Republic of Georgia, the Eliava Institute of Bacteriophage, Microbiology & Virology continues to research the use of phage therapy. Various companies and foundations in North America and Europe are currently researching phage therapies.

Aminoglycoside antibiotics

Aminoglycosides are a group of antibiotics that are effective against certain types of bacteria. They include amikacin, gentamicin, kanamycin, neomycin, netilmicin, paromomycin, streptomycin, tobramycin and apramycin. Those which are derived from Streptomyces genus are named with the suffix -mycin, while those which are derived from micromonospora are named with the suffix -micin.

Mechanism of action

Aminoglycosides work by binding to the bacterial 30S ribosomal subunit (some work by binding to the 50s subunit), inhibiting the translocation of the peptidyl-tRNA from the A-site to the P-site and also causing misreading of mRNA, leaving the bacterium unable to synthesize proteins vital to its growth. But their exact mechanism of action is not fully known.

Spectrum of activity

Aminoglycosides are useful primarily in infections involving aerobic, Gram-negative bacteria, such as Pseudomonas, Acinetobacter, and Enterobacter. In addition, some mycobacteria, including the bacteria that cause tuberculosis, are susceptible to

aminoglycosides. The most frequent use of aminoglycosides is empiric therapy for serious infections such as septicemia, complicated intraabdominal infections, complicated urinary tract infections, and nosocomial respiratory tract infections. Usually, once cultures of the causal organism are grown and their susceptibilities tested, aminoglycosides are discontinued in favor of less toxic antibiotics.

Streptomycin was the first effective drug in the treatment of tuberculosis, though the role of aminoglycosides such as streptomycin and amikacin has been eclipsed (because of their toxicity and inconvenient route of administration) except for multiple drug resistant strains.

Infections caused by Gram-positive bacteria can also be treated with aminoglycosides, but other types of antibiotics are more potent and less damaging to the host. In the past the aminoglycosides have been used in conjunction with beta-lactam antibiotics in streptococcal infections for their synergistic effects, particularly in endocarditis. One of the most frequent combinations is Ampicillin (a beta-lactam, or penicillin-related antibiotic) and Gentamicin. Often, hospital staff refer to this combination as "amp and gent" or more recently called "pen and gent" for penicillin and gentamycin.

Aminoglycosides are mostly ineffective against anaerobic bacteria, fungi and viruses.

Toxicity

Because of their potential for ototoxicity and nephrotoxicity (kidney toxicity), aminoglycosides are administered in doses based on body weight. Blood drug levels and creatinine are monitored during the course of therapy. Serum creatinine measurements are used to estimate how well the kidneys are functioning and as a marker for kidney damage caused by these drugs.

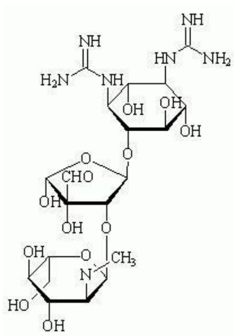
Routes of administration

Since they are not absorbed from the gut, they are administered intravenously and intramuscularly. Some are used in topical preparations for wounds. Oral administration can be used for gut decontamination (e.g. in hepatic encephalopathy).

Specific Agents

- Amikacin (Amikin®) - Gentamicin (Garamycin®) - Kanamycin (Kantrex®) - Neomycin - Netilmicin (Netromycin®) - Streptomycin - Tobramycin (Nebcin®)

Streptomycin



Systematic (IUPAC) name

5-(2,4-diguanidino-3,5,6-trihydroxy-cyclohexoxy)-4- [4,5-dihydroxy-6-(hydroxymethyl)

-3-methylamino-tetrahydropyran-2-yl] oxy-3-hydroxy-2-methyl-tetrahydrofuran-3-carbaldehyde

Identifiers

CAS number 57-92-1

ATC code A07**AA04** J01**GA01**

PubChem 19649

DrugBank APRD00412

Chemical data

Formula $C_{21}H_{39}N_7O_{12}$

Mol. weight 581.574 g/mol

Physical data

Melt. point 12 °C (54 °F)

Streptomycin is an antibiotic drug, the first of a class of drugs called aminoglycosides to be discovered, and was the first antibiotic remedy for tuberculosis. It is derived from the actinobacterium Streptomyces griseus. Streptomycin stops bacterial growth by damaging cell membranes and inhibiting protein synthesis. Specifically, it binds to the 16S rRNA of the bacterial ribosome, which prevents the release of the growing protein (polypeptide chain). Humans have structurally different ribosomes than bacteria, thereby allowing the selectivity of this antibiotic for bacteria. Streptomycin cannot be given orally, but must be administered

by regular intramuscular injection. An adverse effect of this medicine is ototoxicity. It can result in permanent hearing loss.

History

It was first isolated on October 19, 1943 in the laboratory of Selman Abraham Waksman at Rutgers University by Albert Schatz, a graduate student in his laboratory. Waksman and his laboratory discovered several antibiotics, including actinomycin, clavacin, streptothricin, streptomycin, grisein, neomycin, fradicin, candicidin, candidin, and others. Two of these, streptomycin and neomycin, found extensive application in the treatment of numerous infectious diseases. Streptomycin was the first antibiotic that could be used to cure the disease tuberculosis. Waksman is credited with having coined the term antibiotics.

The details and credit for the discovery of streptomycin were strongly contested by Albert Schatz and resulted in litigation. The contention arose because Schatz was the graduate student in charge of performing the lab work on streptomycin; however, it was argued that he was using techniques, equipment and lab space of Waksman's while under Waksman's direction. There is contention as to whether or not Schatz should have been included in the Nobel Prize awarded in 1952. However, the committee stated that the Nobel Prize was awarded not only for the discovery of streptomycin but also for the development of the methods and techniques that led up to its discovery and the discovery of many other antibiotics.

The litigation ended with a settlement for Schatz and the official decision that Waksman and Schatz would be considered co-discoverers of streptomycin. Schatz was awarded the Rutgers medal in 1994, at the age of 74. The controversy ultimately had a negative impact on the careers of both Waksman and Schatz and the controversy continues today.

Uses

- Tuberculosis in combination with other anti-TB drugs
- Yersinia pestis known popularly by one of its varients, the Bubonic Plague has been treated using this, Chloramphenicol, and Tetracycline.

Beta-lactam antibiotics

^{2}-lactam antibiotics are a broad class of antibiotics which include penicillin derivatives, cephalosporins, monobactams, carbapenems and ^{2}-lactamase inhibitors; basically any antibiotic agent which contains a ^{2}-lactam nucleus in its molecular structure. They are the most widely used group of antibiotics available.

Clinical use

^{2}-lactam antibiotics are indicated for the prophylaxis and treatment of bacterial infections caused by susceptible organisms. Whilst traditionally ^{2}-lactam antibiotics were

mainly active only against Gram-positive bacteria, the development of broad-spectrum ²-lactam antibiotics active against various Gram-negative organisms has increased their usefulness.

Mode of action

²-Lactam antibiotics are bactericidal, and act by inhibiting the synthesis of the peptidoglycan layer of bacterial cell walls. The peptidoglycan layer is important for cell wall structural integrity, especially in Gram-positive organisms. The final transpeptidation step in the synthesis of the peptidoglycan is facilitated by transpeptidases known as penicillin binding proteins (PBPs).

²-lactam antibiotics are analogues of D-alanyl-D-alanine - the terminal amino acid residues on the precursor NAM/NAG-peptide subunits of the nascent peptidoglycan layer. The structural similarity between ²-lactam antibiotics and D-alanyl-D-alanine facilitates their binding to the active site of penicillin binding proteins (PBPs). The ²-lactam nucleus of the molecule irreversibly binds to (acylates) the Ser***403*** residue of the PBP active site. This irreversible inhibition of the PBPs prevents the final crosslinking (transpeptidation) of the nascent peptidoglycan layer, disrupting cell wall synthesis. Inhibition of PBPs may also lead to the activation of autolytic enzymes in the bacterial cell wall.

Modes of resistance

By *definition*, all ²-lactam antibiotics have a ²-lactam ring in their structure. The effectiveness of these antibiotics relies on their ability to reach the PBP intact and their ability to bind to the PBP. Hence, there are 2 main modes of bacterial resistance to ²-lactams, as discussed below.

The first mode of ²-lactam resistance is due to enzymatic hydrolysis of the ²-lactam ring. If the bacteria produces the enzymes ²-lactamase or penicillinase, these enzymes will break open the ²-lactam ring of the antibiotic, rendering the antibiotic ineffective. The genes encoding these enzymes may be inherently present on the bacterial chromosome or may be acquired via plasmid transfer, and beta-lactamase gene expression may be induced by exposure to beta-lactams. The production of a ²-lactamase by a bacterium does not necessarily rule out all treatment options with ²-lactam antibiotics. In some instances, ²-lactam antibiotics may be co-administered with a ²-lactamase inhibitor.

However, in all cases where infection with ²-lactamase-producing bacteria is suspected, the choice of a suitable ²-lactam antibiotic should be carefully considered prior to treatment. In particular, choosing appropriate ²-lactam antibiotic therapy is highly important against organisms with inducible ²-lactamase expression. If ²-lactamase production is inducible, then failure to use the most appropriate ²-lactam antibiotic therapy at the onset of treatment will result in induction of ²-lactamase production, thereby making further efforts with other ²-lactam antibiotics more difficult.

The second mode of ²-lactam resistance is due to possession of altered penicillin binding proteins. ²-lactams cannot bind as effectively to these altered PBPs, and as a result, the ²-lactams are less effective at disrupting cell wall synthesis. Notable examples of this mode of resistance include methicillin-resistant Staphylococcus aureus (MRSA) and penicillin-

resistant Streptococcus pneumoniae. Altered PBPs do not necessarily rule out all treatment options with ²-lactam antibiotics.

Common 2-lactam antibiotics

Penicillins

Main article: penicillin

Narrow spectrum penicillins

- benzathine penicillin
- benzylpenicillin **(penicillin G)**
- phenoxymethylpenicillin **(penicillin V)**
- procaine penicillin

Narrow spectrum penicillinase-resistant penicillins

- methicillin
dicloxacillin
flucloxacillin

Moderate spectrum penicillins

- amoxicillin
- ampicillin

Broad spectrum penicillins

- co-amoxiclav (amoxycillin+clavulanic acid)

Extended Spectrum Penicillins

- azlocillin
carbenicillin
ticarcillin

mezlocillin
piperacillin

Cephalosporins

Main article: cephalosporin

First generation cephalosporins

Moderate spectrum.

- cefalexin
- cephalothin
- cefazolin

Second generation cephalosporins

Moderate spectrum with anti-Haemophilus activity.

- cefaclor
- cefuroxime
- cefamandole

Second generation cephamycins

Moderate spectrum with anti-anaerobic activity.

- cefotetan
- cefoxitin

Third generation cephalosporins

Broad spectrum.

- ceftriaxone
- cefotaxime

Broad spectrum with anti-Pseudomonas activity.

- ceftazidime

Fourth generation cephalosporins

Broad spectrum with enhanced activity against Gram positive bacteria and beta-lactamase stability.

- cefepime
- cefpirome

Carbapenems

Main article: carbapenem

Broadest spectrum of beta-lactam antibiotics.

- imipenem (with cilastatin)
- meropenem
- ertapenem
- faropenem

Monobactams

Unlike other beta-lactams, there is no fused ring attached to beta-lactam nucleus. Thus, there is less probability of cross-sensitivity reactions.

- aztreonam (Azactam®)

Beta-lactamase inhibitors

No antimicrobial activity. Their sole purpose is to prevent the inactivation of beta-lactam antibiotics by beta-lactamases, and as such, they are co-administered with beta-lactam antibiotics.

- clavulanic acid
- tazobactam
- sulbactam

Adverse effects

Adverse drug reactions

Common adverse drug reactions (ADRs) for the ^{2}-lactam antibiotics include: diarrhea, nausea, rash, urticaria, superinfection (including candidiasis). (Rossi, 2004)

Infrequent ADRs include: fever, vomiting, erythema, dermatitis, angioedema, pseudomembranous colitis. (Rossi, 2004)

Pain and inflammation at the injection site is also common for parenterally-administered ^{2}-lactam antibiotics.

Allergy/hypersensitivity

Allergic reactions to any ^{2}-lactam antibiotic may occur in up to 10% of patients receiving that agent. Anaphylaxis will occur in approximately 0.01% of patients. (Rossi, 2004) There is perhaps a 5-10% cross-sensitivity between penicillin-derivatives, cephalosporins and carbapenems; but this figure has been challenged by various investigators.

Nevertheless, the risk of cross-reactivity is sufficient to warrant the contraindication of all ²-lactam antibiotics in patients with a history of severe allergic reactions (urticaria, anaphylaxis, interstitial nephritis) to any ²-lactam antibiotic.

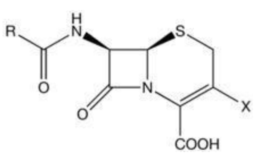
Carbapenem antibiotics

Carbapenems are a class of **beta-lactam antibiotics**.

The following drugs belong to the carbapenem class:

- Imipenem (often given as part of Imipenem/cilastatin) Meropenem
Ertapenem
Faropenem
Doripenem
Panipenem/betamipron

Cephalosporin antibiotics



Cephalosporin nucleus

The *cephalosporins* (IPA: [Ìk[fYloÈspTrYn, Ìs[fY-]) are a class of ²-lactam antibiotics. Together with cephamycins they belong to a sub-group called cephems.

History

Cephalosporin compounds were first isolated from cultures of Cephalosporium acremonium from a sewer in Sardinia in 1948 by Italian scientist Giuseppe Brotzu. He noticed that these cultures produced substances that were effective against Salmonella typhi, the cause of typhoid fever. Researchers at the Sir William Dunn School of Pathology at the University of Oxford isolated cephalosporin C, which had stability to ²-lactamases but was not sufficiently potent for clinical use. The cephalosporin nucleus, 7-aminocephalosporanic acid (7-ACA), was derived from cephalosporin C and proved to be analogous to the penicillin nucleus 6-aminopenicillanic acid. Modification of the 7-ACA side-chains resulted in the development of useful antibiotic agents, and the first agent cephalothin (cefalotin) was launched by Eli Lilly in 1964.

Mode of action

Cephalosporins are bactericidal and have the same mode of action as other beta-lactam antibiotics (such as penicillins). Cephalosporins disrupt the synthesis of the peptidoglycan layer of bacterial cell walls. The peptidoglycan layer is important for cell wall structural integrity, especially in Gram-positive organisms. The final transpeptidation step in the synthesis of the peptidoglycan is facilitated by transpeptidases known as penicillin binding proteins (PBPs).

Clinical use

Indications

Cephalosporins are indicated for the prophylaxis and treatment of bacterial infections caused by susceptible organisms. First-generation cephalosporins are predominantly active against Gram-positive bacteria, and successive generations have increased activity against Gram-negative bacteria (albeit often with reduced activity against Gram-positive organisms).

Adverse effects

Common adverse drug reactions (ADRs) (e1% of patients) associated with cephalosporin therapy include: diarrhea, nausea, rash, electrolyte disturbances, and/or pain and inflammation at injection site. Infrequent ADRs (0.1–1% of patients) include: vomiting, headache, dizziness, oral and vaginal candidiasis, pseudomembranous colitis, superinfection, eosinophilia, and/or fever.

Approximately 5–10% of patients with allergic hypersensitivity to penicillins and/or carbapenems will also have cross-reactivity with cephalosporins. Thus, they are contraindicated in patients with a history of severe of immediate allergic reactions (urticaria, anaphylaxis, interstitial nephritis, etc) to penicillins, carbapenems or cephalosporins.[1]

Classification

The cephalosporin nucleus can be modified to gain different properties. Cephalosporins are sometimes grouped into "generations" by their antimicrobial properties. The first cephalosporins were designated first generation while later, more extended spectrum cephalosporins were classified as second generation cephalosporins. Each newer generation of cephalosporins has significantly greater Gram-negative antimicrobial properties than the preceding generation, in most cases with decreased activity against Gram-positive organisms. Fourth generation cephalosporins, however, have true broad spectrum activity.

The classification of cephalosporins into "generations" is commonly practised, although the exact categorisation of cephalosporins is often imprecise. For example, the fourth generation of cephalosporins is not yet recognized in Japan. In Japan, cefaclor is classed as a first generation cephalosporin; and cefbuperazone, cefminox and cefotetan are classed as second generation cephalosporins. Cefbuperazone, cefminox, and cefotetan are classed as

second generation cephems. Cefmetazole and cefoxitin are classed as third generation cephems. Flomoxef, latamoxef are in a new class called oxacephems.

Most first generation cephalosporins were originally spelt "ceph-" in English-speaking countries. This continues to be the preferred spelling in North America and Australia, while European countries have adopted International Nonproprietary Names, which are usually spelt "cef-". Newer first-generation cephalosporins and all cephalosporins of later generations are spelt "cef-".

First generation

First generation cephalosporins are moderate spectrum agents, with a spectrum of activity that includes penicillinase-producing, methicillin-susceptible staphylococci and streptococci, though they are not the drugs of choice for such infections. They also have activity against some Escherichia coli, Klebsiella pneumoniae and Proteus mirabilis, but have no activity against Bacteroides fragilis, enterococci, methicilllin-resistant staphylococci, Pseudomonas, Acinetobacter, Enterobacter, indole-positive Proteus or Serratia.

- Cefacetrile (cephacetrile)

Cefadroxil (cefadroxyl; Duricef®)
Cefalexin (cephalexin; Keflex®)
Cephaloglycin
Cefalonium (cephalonium)
Cefaloridine (cephaloradine)
Cefalotin (cephalothin; Keflin®)
Cefapirin (cephapirin; Cefadryl®)
Cefatrizine
Cefazaflur
Cefazedone
Cefazolin (cephazolin; Ancef®, Kefzol®)
Cefradine (cephradine; Velosef®)
Cefroxadine
Ceftezole

Second generation

The second generation cephalosporins have a greater Gram-negative spectrum while retaining some activity against Gram-positive cocci. They are also more resistant to beta-lactamase.

- Cefaclor (Ceclor®)

Cefonicid (Monocid®)
Cefprozil (cefproxil; Cefzil®)
Cefuroxime (Zinnat®, Zinacef®, Ceftin®)
Cefuzonam

Second generation cephalosporins with antianaerobe activity

- Cefamandole
Ceforanide
Cefotiam

The following cephems are also sometimes grouped with second-generation cephalosporins:

- Carbacephems: loracarbef (Lorabid®)
Cephamycins: cefbuperazone, cefmetazole (Zefazone®), cefminox, cefotetan (Cefotan®), cefoxitin (Mefoxin®)

Third generation

Third generation cephalosporins have a broad spectrum of activity and further increased activity against Gram-negative organisms. Some members of this group (particularly those available in an oral formulation, and those with anti-pseudomonal activity) have decreased activity against Gram-positive organisms. They may be particularly useful in treating hospital-acquired infections, although increasing levels of extended-spectrum beta-lactamases are reducing the clinical utility of this class of antibiotics.

- Cefcapene
Cefdaloxime
Cefdinir (Omnicef®)
Cefditoren
Cefetamet
Cefixime (Suprax®)
Cefmenoxime
Cefodizime
Cefoperazone (Cefobid®)
Cefotaxime (Claforan®)
Cefpimizole
Cefpodoxime (Vantin®)
Cefteram
Ceftibuten (Cedax®)
Ceftiofur
Ceftiolene
Ceftizoxime (Cefizax®)
Ceftriaxone (Rocephin®)

Third generation cephalosporins with antipseudomonal activity

- Ceftazidime (Fortum®, Fortaz®)
Cefpiramide
Cefsulodin

The following cephems are also sometimes grouped with third-generation cephalosporins:

- Oxacephems: latamoxef (moxalactam)

Fourth generation

Fourth generation cephalosporins are extended-spectrum agents with similar activity against Gram-positive organisms as first-generation cephalosporins. They also have a greater resistance to beta-lactamases than the third generation cephalosporins. Many can cross blood brain barrier and are effective in meningitis.

- Cefclidine
Cefepime (Maxipime®)
Cefluprenam
Cefoselis
Cefozopran
Cefpirome
Cefquinome

The following cephems are also sometimes grouped with third-generation cephalosporins:

- Oxacephems: flomoxef

Yet to be classified

These cephems have progressed far enough to be named, but have not been assigned to a particular generation. Ceftobiprole (and the oral medocaril version) are on the FDA fast track. Ceftobiprole has powerful antipseudomonal characteristics and appears to be less susceptible to development of resistance.

- Cefaclomezine
Cefaloram
Cefaparole
Cefcanel
Cefedrolor
Cefempidone
Cefetrizole
Cefivitril
Cefmatilen
Cefmepidium
Cefovecin
Cefoxazole
Cefrotil
Cefsumide
Ceftioxide
Ceftobiprole (previously BAL 9141 and RO 63-9141)
Ceftobiprole (previously BAL 5788)
Cefuracetime

- Beta-lactam antibiotic

AGG01

AGG01 is the tentative name of a new Penicillin-class antibiotic, recently as of October 2006 discovered in the breast milk of the Tammar Wallaby, reportedly one hundred times more powerful than penicillin.

This compound was found to be effective against MRSA, E. coli, Streptococci, Salmonella, Bacillus subtilus, Pseudomonas spp, Proteus vulgaris, and Staphylococcus aureus.

AGG01 has not yet been classified as a Beta-lactam antibiotic.

AGG01 is a cationic peptide, which is a polycationic protein which is rich in positive residues of the amino acidss arginine and lysine, and which folds into an amphipathic structure (one which has both hydrophobic and hydrophilic areas). These features mean that it can interact with the anionic lipids in the bacterial membrane, such as phosphatidylglycerol. It inserts itself into the membrane, by competing with cross-linking proteins between each membrane layer, and then sets up trans-membrane protein channels which induce ion transport out of the cell. This causes huge leakage via osmosis through these 'pores' and the general consensus is that the loss of these essential molecules is the mechanism by which bacteria are killed. The bacterial membrane has a different structure from the mammalian plasma membrane, so the protein can only kill pathogenic cells and not human ones.[1]

Therapeutic considerations

Pregnancy cat. A$_{(AU)}$

Legal status POM$_{(UK)}$

Routes oral, intravenous

Amoxicillin (INN) or *amoxycillin* (former BAN) is a moderate-spectrum ^{2}-lactam antibiotic used to treat bacterial infections caused by susceptible microorganisms. It is usually the drug of choice within the class because it is better absorbed, following oral administration, than other beta-lactam antibiotics. Amoxicillin is susceptible to degradation by ^{2}-lactamase-producing bacteria, and so may be given with clavulanic acid to decrease its susceptibility (see below). It is currently marketed by GlaxoSmithKline under the trade name *Amoxil*.

Mode of action

Amoxicillin acts by inhibiting the synthesis of bacterial cell walls. It inhibits cross-linkage between the linear peptidoglycan polymer chains that make up a major component of the cell wall of Gram-positive bacteria.

Main article: beta-lactam antibiotic

Microbiology

Amoxicillin is a moderate-spectrum antibiotic active against a wide range of Gram-positive, and a limited range of Gram-negative organisms. Some examples of susceptible and resistant organisms, from the Amoxil® Approved Product Information (GSK, 2003), are listed below.

Susceptible Gram-positive organisms

Streptococcus spp., Diplococcus pneumoniae, non ²-lactamase-producing Staphylococcus spp., and Streptococcus faecalis.

Susceptible Gram-negative organisms

Haemophilus influenzae, Neisseria gonorrhoeae, Neisseria meningitidis, Escherichia coli, Proteus mirabilis and Salmonella spp.

Resistant organisms

Penicillinase-producing organisms, particularly penicillinase-producing Staphylococcus spp. Penicillinase-producing N. gonorrhoeae and H. influenzae are also resistant.

All strains of Pseudomonas spp., Klebsiella spp., Enterobacter spp., indole-positive Proteus spp., Serratia marcescens, and Citrobacter spp. are resistant.

The incidence of ²-lactamase-producing resistant organisms, including E. coli, appears to be increasing.

Doubling the routinely given concentration (in pediatrics) of amoxicillin has been shown to eradicate intermediately resistant organisms (Red Book, 2003 Report of the Committee on Infectious Diseases, American Academy of Pediatrics).

Formulations

Amoxicillin in trihydrate form is available as capsules, tablets, or syrup for oral use, and as the sodium salt for intravenous administration. It is one of the most common antibiotics issued to children.

Amoxicillin and clavulanic acid

Main article: Co-amoxiclav

Amoxicillin (in either trihydrate or sodium salt forms) may be combined with Clavulanic acid (as potassium clavulanate), a ²-lactamase inhibitor, to increase the spectrum of action against Gram-negative organisms, and to overcome bacterial antibiotic resistance mediated through ²-lactamase production. This formulation is referred to as Co-amoxiclav (British Approved Name), but commonly by proprietary names such as Augmentin and Clamoxyl.

Side Effects

Side effects are as those for Beta-lactam antibiotic Adverse effects.

Proprietary preparations

The patent for amoxicillin has expired. Thus amoxicillin is marketed under many trade names including: Actimoxi®, Amoksiklav®, Amoxibiotic®, Amoxicilina®, Apo-Amoxi®, Cilamox®, Dispermox®, Isimoxin®, Lamoxy®, Ospamox®, Pamoxicillin®, Polymox®, Sinacilin®, Trimox®, Tolodina®, Wymox®, Zerrsox® and Zimox®.

Trivia

Amoxicillin is often known for its unappealing taste and odor.

Routes Oral, intravenous

Ampicillin is a beta-lactam antibiotic that has been used extensively to treat bacterial infections since 1961. It can sometimes result in allergic reactions that range in severity from a rash (i.e. patients with mononucleosis) to potentially lethal anaphylaxis.

Mechanism of action

Belonging to the group of beta-lactam antibiotics, ampicillin is able to penetrate Gram-positive and some Gram-negative bacteria. It inhibits the third and final stage of bacterial cell wall synthesis, which ultimately leads to cell lysis.

Indications

Ampicillin is closely related to amoxicillin, another type of penicillin, and both are used to treat urinary tract infections, otitis media, uncomplicated community-acquired pneumonia, Haemophilus influenzae, salmonellosis and Listeria meningitis. It is used with flucloxacillin in the combination antibiotic co-fluampicil for empiric treatment of cellulitis; providing cover against Group A streptococcal infection whilst the flucloxacillin acts against the Staphylococcus aureus bacterium. Of concern is the number of bacteria that become resistant to Ampicillin necessitating combination therapy or use of other antibiotics.

Use in research

Ampicillin is often used in molecular biology as a test for the uptake of genes (e.g., by plasmids) by bacteria (e.g., E. coli). A gene that is to be inserted into a bacterium is coupled to a gene coding for an ampicillin resistance (in E. coli, usually the bla gene, coding for ²-lactamase). The treated bacteria are then grown on a medium containing ampicillin. Only the bacteria that successfully take up the desired genes become ampicillin resistant, and therefore contain the other desired gene as well.

Co-amoxiclav

Co-amoxiclav is the British Approved Name, in the British Pharmacopoeia, for the combination antibiotic containing Amoxicillin (as either trihydate or the sodium salt) and Clavulanic acid (as Potassium clavulanate). This name, unlike co-trimoxazole, has not been widely adopted internationally and the combination product is usually referred to by various names such as *amoxicillin with clavulanic acid* or *amoxicillin+clavulanate* or simply by the trade name. Co-amoxiclav is currently marketed under various trade names including *Augmentin* (GlaxoSmithKline), and for veterinary use as *Clavamox* (Pfizer) and *Clavaseptin* (Vétoquinol).

The combination of amoxicillin, a ^{2}-lactam antibiotic; with clavulanic acid, a ^{2}-lactamase inhibitor; results in an antibiotic with an increased spectrum of action and restored efficacy against ^{2}-lactamase producing amoxicillin-resistant bacteria.

Dosage

The proportions of the two constituents are expressed as x/y where x and y are the strengths in milligrams of amoxicillin and clavulanic acid respectively. However, the branded products indicate their strengths as the total combined antibiotic quantity, hence co-amoxiclav 250/125 a Augmentin 375 and contains 250 mg of amoxicillin with 125 mg of clavulanic acid.

Standard adult dosages for respiratory tract, urinary, abdominal and dental infections as well as cellulitis and animal bites is co-amoxiclav 250/125 (one tablet Augmentin 375) taken every 8 hours, which may be doubled in severe infections (either as two tablets at a time of Augmentin 375, or a single tablet of co-amoxiclav 500/125 a Augmentin 625). In the US, Augmentin XR (co-amoxiclav 1000/62.5) is marketed for use in community acquired pneumonia with two tablets taken twice a day (giving 4000 mg total daily dose of amoxicillin).

Dosages for children are also given three times a day using suspensions containing co-amoxiclav 250/62 in each 5 mL (Augmentin '250/62 SF') for those between the ages of 6 - 12 years and co-amoxiclav 125/31 (Augmentin '125/31 SF') for those between the ages of 1 - 6 years. A more concentrated solution, co-amoxiclav 400/57 (Augmentin Duo), may be administered more conveniently just twice daily to children from as young as 2 months of age; quantities are based on body weight with 2.5 mL from the age of 2 years and 5 mL after the age of 6 years.

Side effects

Amongst the possible side-effects of this medication are diarrhoea, vomiting and a few other conditions. These do not usually require medical attention. However, if the patient experiences an allergic reaction to the medication, jaundice, fever or severe diarrhoea, it is necessary to contact a doctor immediately. As with all antimicrobial agents, pseudomembranous colitis has been associated with the use of amoxicillin-clavulanate.

Amoxicillin is a member of the penicillin family of antibiotics, and therefore should not be taken by patients allergic to penicillin.

Veterinary use

The amoxicillin/clavulanic acid combination is also used in the treatment of, amongst other infections, periodontitis in dogs and skin infections in cats. The preparation for veterinary use is commonly marketed under the trade names *Clavaseptin*, and *Clavamox*.

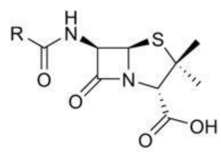
Penicillin



Penicillin nucleus

Penicillin (sometimes abbreviated *PCN*) refers to a group of ²-lactam antibiotics used in the treatment of bacterial infections caused by susceptible, usually Gram-positive, organisms. The name “penicillin” can also be used in reference to a specific member of the penicillin group. All penicillins possess the basic Penam Skeleton, which has the molecular formula R-C9H11N2O4S, where R is a variable side chain.

History

The discovery of penicillin is usually attributed to Scottish scientist Alexander Fleming in 1928, though others had earlier noted the antibacterial effects of Penicillium. Fleming, at his laboratory in St. Mary's Hospital (Now one of Imperial College teaching hospitals) in London, noticed a halo of inhibition of bacterial growth around a contaminant blue-green mould on a Staphylococcus plate culture. Fleming concluded that the mould was releasing a substance that was inhibiting bacterial growth and lysing the bacteria. He grew a pure culture of the mould and discovered that it was a Penicillium mould, now known to be Penicillium chrysogenum. Fleming coined the term "penicillin" to describe the filtrate of a broth culture of the Penicillium mould. Even in these early stages, penicillin was found to be most effective against Gram-positive bacteria, and ineffective against Gram-negative organisms and fungi. He expressed initial optimism that penicillin would be a useful disinfectant, being highly potent with minimal toxicity compared to antiseptics of the day, but particularly noted its laboratory value in the isolation of "Bacillus influenzae" (now Haemophilus influenzae).[1] After further experiments, Fleming was convinced that penicillin could not last long enough in the human body to kill pathogenic bacteria and stopped studying penicillin after 1931, but

restarted some clinical trials in 1934 and continued to try to get someone to purify it until 1940.

In 1939, Australian scientist Howard Walter Florey and a team of researchers (Ernst Boris Chain, A. D. Gardner, Norman Heatley, M. Jennings, J. Orr-Ewing and G. Sanders) at the Sir William Dunn School of Pathology, University of Oxford made significant progress in showing the in vivo bactericidal action of penicillin. Their attempts to treat humans failed due to insufficient volumes of penicillin, but they proved its harmlessness and effect in mice. Some of the pioneering trials of penicillin took place at the Radcliffe Infirmary in Oxford. On 1942-03-14 John Bumstead and Orvan Hess became the first in the world to successfully treat a patient using penicillin.[2][3]

During World War II, penicillin made a major difference in the number of deaths and amputations caused by infected wounds amongst Allied forces. Availability was severely limited, however, by the difficulty of manufacturing large quantities of penicillin and by the rapid renal clearance of the drug necessitating frequent dosing. Penicillins are actively secreted and about 80% of a penicillin dose is cleared within three to four hours of administration. During those times it became common procedure to collect the urine from patients being treated so that the penicillin could be isolated and reused.[4]

This was not a satisfactory solution, however, so researchers looked for a way to slow penicillin secretion. They hoped to find a molecule that could compete with penicillin for the organic acid transporter responsible for secretion such that the transporter would preferentially secrete the competitive inhibitor. The uricosuric agent probenecid proved to be suitable. When probenecid and penicillin are concomitantly administered, probenecid competitively inhibits the secretion of penicillin, increasing its concentration and prolonging its activity. The advent of mass-production techniques and semi-synthetic penicillins solved supply issues, and this use of probenecid declined.[4] Probenecid is still clinically useful, however, for certain infections requiring particularly high concentrations of penicillins.[5]

The chemical structure of penicillin was determined by Dorothy Crowfoot Hodgkin in the early 1940s, enabling synthetic production. A team of Oxford research scientists led by Australian Howard Walter Florey and including Ernst Boris Chain and Norman Heatley discovered a method of mass producing the drug. Florey and Chain shared the 1945 Nobel prize in medicine with Fleming for this work. Penicillin has since become the most widely used antibiotic to date and is still used for many Gram-positive bacterial infections. Alexander Fleming has also discovered that tears have bacteria killing cells in them which cause no physical damage to the body.

Developments from penicillin

The narrow spectrum of activity of the penicillins, along with the poor activity of the orally-active phenoxymethylpenicillin, led to the search for derivatives of penicillin which could treat a wider range of infections.

The first major development was ampicillin, which offered a broader spectrum of activity than either of the original penicillins and allowed doctors to treat a broader range of both and Further development yielded beta-lactmase-resistant penicillins including flucloxacillin, dicloxacillin and methicillin. These were important for their activity against beta-lactamase-

producing bacteria species, but are ineffective against the methicillin-resistant Staphylococcus aureus strains that subsequently emerged.

The line of true penicillins were the antipseudomonal penicillins, such as ticarcillin and piperacillin, useful for their activity against Gram-negative bacteria. However, the usefulness of the beta-lactam ring was such that related antibiotics, including the mecillinams, the carbapenems and, most importantly, the cephalosporins, have at the centre of their structures.

Mode of action

Main article: beta-lactam antibiotic

^{2}-lactam antibiotics work by inhibiting the formation of peptidoglycan cross links in the bacterial cell wall. The ^{2}-lactam moiety of penicillin binds to the enzyme (transpeptidase) that links the peptidoglycan molecules in bacteria, and this weakens the cell wall of the bacterium when it multiplies (in other words, the antibiotic causes cell cytolysis or death when the bacterium tries to divide). Scott Williams is generally credited with having postulated this hypothesis. In addition, the build-up of peptidoglycan precursors triggers the activation of bacterial cell wall hydrolases which further digest the bacteria's existing peptidoglycan.

In addition to the quadraceptics of mechanics, the bacterial wall can break down.

Variants in clinical use

The term “penicillin” is often used generically to refer to one of the narrow-spectrum penicillins, particularly benzylpenicillin.

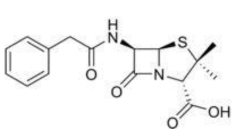
Benzathine benzylpenicillin

Benzathine benzylpenicillin (rINN), also known as *benzathine penicillin*, is slowly absorbed into the circulation, after intramuscular injection, and hydrolysed to benzylpenicillin in vivo. It is the drug-of-choice when prolonged low concentrations of benzylpenicillin are required and appropriate, allowing prolonged antibiotic action over 2–4 weeks after a single IM dose. It is marketed by Wyeth under the trade name *Bicillin L-A*.

Specific indications for benzathine pencillin include: (Rossi, 2004)

- Prophylaxis of rheumatic fever
Early or latent syphilis

Benzylpenicillin (penicillin G)



Penicillin G (Benzylpenicillin)

Benzylpenicillin, commonly known as *penicillin G*, is the gold standard penicillin. Penicillin G is typically given by a parenteral route of administration because it is unstable in the hydrochloric acid of the stomach. Because the drug is given parenterally, higher tissue concentrations of penicillin G can be achieved than is possible with phenoxymethylpenicillin. These higher concentrations translate to increased antibacterial activity.

Specific indications for benzylpenicillin include: (Rossi, 2004)

- Bacterial endocarditis

Meningitis
Aspiration pneumonia, lung abscess
Community-acquired pneumonia
Syphilis
Septicaemia in children

Phenoxymethylpenicillin (penicillin V)

Phenoxymethylpenicillin, commonly known as *penicillin V*, is the orally-active form of penicillin. It is less active than benzylpenicillin, however, and is only appropriate in conditions where high tissue concentrations are not required.

Specific indications for phenoxymethylpenicillin include: (Rossi, 2004)

- Infections caused by Streptococcus pyogenes
  - Tonsilitis

Pharyngitis
Skin infections

- Prophylaxis of rheumatic fever

Moderate-to-severe gingivitis (with metronidazole)

Procaine benzylpenicillin

Procaine benzylpenicillin (rINN), also known as *procaine penicillin*, is a combination of benzylpenicillin with the local anaesthetic agent procaine. Following deep intramuscular injection, it is slowly absorbed into the circulation and hydrolysed to benzylpenicillin — thus it is used where prolonged low concentrations of benzylpenicillin are required.

This combination is aimed at reducing the pain and discomfort associated with a large intramuscular injection of penicillin. It is widely used in veterinary settings.

Specific indications for procaine penicillin include: (Rossi, 2006)

- Syphilis

Respiratory tract infections where compliance with oral treatment is unlikely
Cellulitis, erysipelas

Procaine penicillin is also used as an adjunct in the treatment of anthrax.

Semi-synthetic penicillins

Structural modifications were made to the side chain of the penicillin nucleus in an effort to improve oral bioavailability, improve stability to beta-lactamase activity, and increase the spectrum of action.

Narrow spectrum penicillinase-resistant penicillins

This group was developed to be effective against beta-lactamases produced by Staphylococcus aureus, and are occasionally known as anti-staphylococcal penicillins.

- Methicillin
Dicloxacillin
Flucloxacillin
Oxacillin

Moderate spectrum penicillins

This group was developed to increase the spectrum of action and, in the case of amoxicillin, improve oral bioavailability.

- Amoxicillin

- Ampicillin

Extended Spectrum Penicillins

This group was developed to increase efficacy against Gram-negative organisms. Some members of this group also display activity against Pseudomonas aeruginosa.

- Piperacillin
Ticarcillin
Azlocillin
Carbenicillin

Penicillins with beta-lactamase inhibitors

Penicillins may be combined with beta-lactamase inhibitors to increase efficacy against ^{2}-lactamase-producing organisms. The addition of the beta-lactamase inhibitor does not generally, in itself, increase the spectrum of the partner penicillin.

- Amoxicillin/clavulanic acid

- Ampicillin/sulbactam
Ticarcillin/clavulanic acid
Piperacillin/tazobactam

Adverse effects

Adverse drug reactions

Common adverse drug reactions (e1% of patients) associated with use of the penicillins include: diarrhea, nausea, rash, urticaria, and/or superinfection (including candidiasis). Infrequent adverse effects (0.1–1% of patients) include: fever, vomiting, erythema, dermatitis, angioedema, and/or pseudomembranous colitis.[5]

Pain and inflammation at the injection site is also common for parenterally-administered benzathine benzylpenicillin, benzylpenicillin, and to a lesser extent procaine benzylpenicillin.

Allergy/hypersensitivity

Allergic reactions to any ^{2}-lactam antibiotic may occur in up to 10% of patients receiving that agent. Anaphylaxis will occur in approximately 0.01% of patients.[5] There is perhaps a 5-10% cross-sensitivity between penicillin-derivatives, cephalosporins and carbapenems; but this figure has been challenged by various investigators.

Nevertheless, the risk of cross-reactivity is sufficient to warrant the contraindication of all ^{2}-lactam antibiotics in patients with a history of severe allergic reactions (urticaria, anaphylaxis, interstitial nephritis) to any ^{2}-lactam antibiotic.

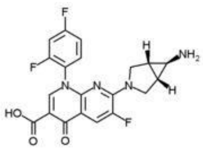
Fluoroquinolone antibiotics



Trovafloxacin

The *quinolones* are a family of broad-spectrum antibiotics. The parent of the group is nalidixic acid. The majority of quinolones in clinical use belong to the subset of *fluoroquinolones*, which have a fluoro group attached the central ring system.

Mechanism

Quinolones and fluoroquinolones are bactericidal drugs, actively killing bacteria. Quinolones inhibit the bacterial DNA gyrase or the topoisomerase IV enzyme, thereby inhibiting DNA replication and transcription. Quinolones can enter cells easily and therefore are often used to treat intracellular pathogens such as Legionella pneumophila and Bacillus anthracis.

Adverse effects

Quinolone antibiotics were once considered relatively safe, but several side effects have become evident with experience. For example, numerous case reports have implicated their use since 1965 in spontaneous tendon ruptures or damage, especially with the concurrent use of a systemic corticosteroid. In the fall of 2004, the Food and Drug Administration upgraded the warnings found within the package inserts for all drugs within this class regarding such serious adverse reactions.

- Peripheral neuropathy (irreversible nerve damage): "Rare cases of sensory or sensor motor axonal polyneuropathy affecting small and or large axons resulting in paresthesias, hypoaesthesias, dysesthesias, and weakness have been reported in patients taking quinolones. Therapy should be discontinued if the patient experiences symptoms of neuropathy including pain, burning, tingling, numbness and or weakness or is found to have deficits in light touch, pain, temperature, position sense, vibratory sensation, and or motor strength in order to prevent the development of an irreversible condition."
- Tendon damage: "Ruptures of the shoulder, hand, Achilles tendon or other tendons that require surgical repair or resulted in prolonged disability have been reported in patients receiving quinolones. Post-marketing surveillance reports indicate that this risk may be increased in patients receiving concomitant corticosteroids, especially the elderly. Fluoroquinolone therapy should be discontinued if the patient experiences pain, inflammation, or rupture of a tendon. Patients should rest and refrain from exercise until diagnosis of tendonitis or tendon rupture had been excluded. Tendon rupture can occur during or after therapy with quinolones."

Other problems include:

- Heart problems (prolonged QT Interval / Torsades de pointes)

Pseudomembranous colitis
Rhabdomyolysis (muscle wasting)
Stevens-Johnson syndrome
Lowered seizure threshold

Resistance

Resistance to quinolones can develop rapidly, even during a course of treatment. Numerous pathogens, including Staphylococcus aureus, enterococci, Pseudomonas aeruginosa, and Streptococcus pyogenes now exhibit resistance worldwide.[1] Widespread veterinary usage of quinolones, particularly in Europe, has been implicated.

Generations

The quinolones are divided into generations based on their antibacterial spectrum. The earlier generation agents are generally more narrow spectrum than the later ones.

1st generation

- cinoxacin (Cinoxacin®)

flumequine (Flubactin®) (*Veterinary use*)
nalidixic acid (NegGam®, Wintomylon®)
oxolinic acid
piromidic acid
pipemidic acid

2nd generation

- ciprofloxacin (Cipro®, Ciproxin®)
- enoxacin (Enroxil®, Penetrex®)

fleroxacin (Megalone®)
levofloxacin (Cravit®, Levaquin®, Quixin®)
lomefloxacin (Maxaquin®)
nadifloxacin
norfloxacin (Noroxin®, Quinabic®, Janacin®)
ofloxacin (Floxin®, Oxaldin®, Tarivid®)
pefloxacin
rufloxacin

3rd generation

- balofloxacin

gatifloxacin (Tequin®)
grepafloxacin (Raxar®)
pazufloxacin Mesilate
sparfloxacin (Zagam®)
temafloxacin
tosufloxacin

4th generation

- clinafloxacin

gemifloxacin (Factive®)
moxifloxacin (Avelox®)
Gatifloxacin (Zymar®)
sitafloxacin
trovafloxacin (Trovan®)

In development

- ecinofloxacin

prulifloxacin

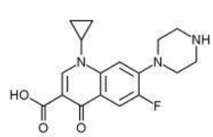
Veterinary use

The quinolones have been widely used in agriculture and several agents exist which have veterinary but not human use.

- danofloxacin (Advocin®, Advocid®) (*Veterinary use*)

difloxacin (Dicural®, Vetequinon®)
enrofloxacin (Baytril®)
marbofloxacin (Marbocyl®, Zenequin®) (*Veterinary use*)
orbifloxacin (Orbax®, Victas®) (*Veterinary use*)
sarafloxacin (Floxasol®, Saraflox®, Sarafin®) (*Veterinary use*)

Ciprofloxacin



Systematic (IUPAC) name

1-cyclopropyl-6-fluoro-4-oxo-7-piperazin-1-yl-quinoline-3-carboxylic acid

Therapeutic considerations

Pregnancy cat. B3 (Australia), C (USA)

Legal status Schedule 4 (Australia), Prescription Only (UK)

Routes Oral, intravenous, topical (ear drops, eye drops)

Ciprofloxacin is the generic international name for the synthetic antibiotic manufactured and sold by Bayer Pharmaceutical under the brand names *Cipro*® and *Ciproxin*® (and other brand names in other markets, e.g. veterinary drugs), belonging to a group called fluoroquinolones. Ciprofloxacin is bactericidal. Its mode of action depends upon blocking bacterial DNA replication by binding itself to an enzyme called DNA gyrase, thereby preventing the enzyme's ability to untwist the DNA double helix, which is required for DNA replication.

Activity

Ciprofloxacin is a broad-spectrum antibiotic that is active against both Gram-positive and Gram-negative bacteria.

- Enterobacteriaceae

Vibrio

Haemophilus influenzae
Neisseria gonorrhoeae
Neisseria meningitidis
Moraxella catarrhalis
Brucella
Campylobacter
Mycobacterium intracellulare
Legionella sp.
Pseudomonas aeruginosa
Bacillus anthracis - that causes anthrax

Weak activity against:

- Streptococcus pneumoniae

Chlamydia trachomatis
Chlamydia pneumoniae

No activity against:

- Bacteroides

Burkholderia cepacia
Enterococcus faecium
Ureaplasma urealyticum

- and others

The major adverse effect seen with use of is gastrointestinal irritation, common with many antibiotics. Because of its general safety, potency and broad spectrum activity, ciprofloxacin was initially reserved as a "last-resort" drug for use on difficult and drug-resistant infections. As with any antibiotic, however, increasing time and usage has led to an increase in ciprofloxacin-resistant infections, mainly in the hospital setting. Also implicated in the rise of resistant bacteria is the use of lower-cost, less potent fluoroquinolones, and the widespread addition of ciprofloxacin and other antibiotics to the feed of farm animals, which leads to greater and more rapid weight gain, for reasons which are not clear.

In cell culture it is used to treat infection with mycoplasma.

Label information

The drug is available for oral and parenteral use. It is used in lower respiratory infections (pneumonias), urinary tract infections, STDs, septicemias, Legionellosis and atypical Mycobacterioses. Dosage in respiratory infections is 500-1500 mg a day in 2 doses.

It is contraindicated in children, pregnancy, and in patients with epilepsy. Dose adjustment or avoidance may be necessary with liver or renal failure.

Ciprofloxacin can cause photosensitivity reactions and can elevate plasma theophylline levels to toxic values. It can also cause constipation and sensitivity to caffeine. Ciprofloxacin is also known to cause swelling of certain joints and cartilage.

Interactions

Quercetin, a flavonoid occasionally used as a dietary supplement may interact with fluroquinolones, as quercetin competitively binds to bacterial DNA gyrase. Some foods such

as garlic and apples contain high levels of quercetin. Whether this inhibits or enhances the effect of fluoroquinolones is not entirely clear.[2]

Contraindications

Metal cations such as aluminium, magnesium, calcium, ferrous sulfate, and zinc are thought to form chelation complexes with fluoroquinolone antibiotics and prevent the drugs from being absorbed. Because of this, avoid taking antacids which contain aluminium, magnesium or calcium with ciprofloxacin. Sucralfate, which has a high aluminium content, also reduces the bioavailability of ciprofloxacin to approximately 4%[3]. Ciprofloxacin may be taken with meals or on an empty stomach. Ciprofloxacin should not be taken with dairy products or calcium-fortified juices alone, but may be taken with a meal that contains these products.[4]

Heavy exercise is discouraged, as achilles tendon rupture has been reported in patients taking ciprofloxacin. Achilles tendon rupture due to ciprofloxacin use is typically associated with renal failure.

The toxicity of drugs that are metabolised by the cytochrome P450 system is enhanced by concomitant use of some quinolones. They may also interact with the GABA A receptor and cause neurological symptoms; this is further augmented by certain non-steroidal anti-inflammatory drugs.[5]

Fluoroquinolones are increasingly contraindicated for patients who have been to S.E. Asia due to the growing prevalance of antibiotic resistance to the class of antibiotics in that region. [6]

Dosing

Ciprofloxacin is available in oral tablets (250, 500, 650, and 1000 mg), as well as ready-made infusion bottles (200 and 400 mg). A combination preparation of ciprofloxacin 500 mg and tinidazole 600 mg is marketed under the name *Ciplox-TZ®* for infections where anaerobes or protozoa together with ciprofloxacin-sensitive aerobes are likely.

Due to its elimination half-life, ciprofloxacin is administered twice daily. No dose adjustments are generally required for mild to moderate renal impairment.

Business aspects

The discovery and development of ciprofloxacin is that rare case of an actual groundbreaking new drug development, opening up an entire new class of antibiotics for further research, development, and marketing. Even more remarkable, it seems to be a case where the first drug discovered of this class remains the 'gold standard' in terms of efficacy, with the other drugs developed by other pharmaceutical companies relegated to 'me-too' status and forced to compete on the basis of lower cost.

Encouraged by the magnitude of this success, as well as the influx of cash, Bayer Pharmaceutical embarked on a plan to remake itself from a minor pharmaceutical manufacturer into a major player in the international pharmaceutical business, with a lock on the antibiotic field. Unfortunately, a combination of the tendency for antibiotics to be

viewed as a commodity and prescribed on the basis of lowest cost, Bayer's inability to follow up with another 'blockbuster' discovery, and a general downturn in the international pharmaceutical business forced Bayer into a major downsizing in 2000-2001. Faced with the imminent expiry of its patent rights to ciprofloxacin in the early 2000's and the predictable loss of market share to generic ciprofloxacin, Bayer has resorted to the usual strategy of pharmaceutical companies in such a situation; focus on the development and patenting of new variations of the old drug (i.e. pediatric ciprofloxacin, intravenous ciprofloxacin, once-a-day ciprofloxacin, etc.), which will have the side effect of extending the patent on the original drug.

"Cipro" became a household word during the 2001 anthrax attacks after the destruction of the World Trade Center. Bayer took a severe financial blow from the costs involved in rapidly increasing production of the drug to be sold to the American government at far below market price.

Generic ciprofloxacin is now available in many markets around the world including the USA. In addition two new once daily formulations have been launched in the USA. Bayer have marketed Cipro XR which is an extended release formulation. Meanwhile Depomed have developed ProQuin XR another once daily formulation of ciprofloxacin which uses a gastric retention polymer technology to slow the release of ciprofloxacin into the blood.

Ciprofloxacin is the third largest selling molecule in Pakistan pharmaceutical market. It is marketed by numerous companies. In Pakistan, Highnoon Laboratories Ltd. markets the brand under the name "Cyrocin".

Glycopeptide antibiotics

Glycopeptide antibiotics are a class of antibiotic drugs. They consist of a glycosylated cyclic or polycyclic nonribosomal peptide. Important glycopeptide antibiotics include vancomycin, teicoplanin, ramoplanin, and decaplanin.

This class of drugs inhibit the synthesis of cell walls in susceptible microbes by inhibiting peptidoglycan synthesis. Due to their toxicity, their use is restricted to those patients who are critically ill or who have a demonstrated hypersensitivity to the ²-lactams. Principally effective against gram positive cocci, they exhibit a narrow spectrum of action. They are the last effective line of defense for cases of Methicillin-resistant Staphylococcus aureus.

Vancomycin is usually given intravenously and can cause tissue necrosis and phlebitis at the injection site if given too rapidly. Indeed pain at site of injection is a common adverse event.

Routes IV, oral

Vancomycin (INN) (IPA: [ÌvæKkoÈmajsYn]) is a glycopeptide antibiotic used in the prophylaxis and treatment of infections caused by Gram-positive bacteria. It has traditionally been reserved as a drug of "last resort", used only after treatment with other antibiotics had failed, although the emergence of vancomycin-resistant organisms means that it is increasingly being displaced from this role by linezolid and the carbapenems.

It was developed by Eli Lilly, which marketed *vancomycin hydrochloride* under the trade name *Vancocin*. In 2004, Eli Lilly licensed Vancocin to ViroPharma in the U.S., Flynn Pharma in the UK and Aspen Pharmacare in Australia. The patent expired in the early 1980s and generic versions of the drug are also available under various trade names.

Pharmacology and chemistry

It is a branched tricyclic glycosylated nonribosomal peptide produced by the fermentation of the Actinobacteria species Amycolatopsis orientalis (formerly designated [Nocardia orientalis](#)).

Vancomycin acts by inhibiting proper cell wall synthesis in Gram-positive bacteria. The mechanism inhibited, and various factors related to entering the outer membrane of Gram-negative organisms mean that vancomycin is not active against Gram-negative bacteria (except some non-gonococcal species of Neisseria).

Specifically, vancomycin prevents incorporation of N-acetylmuramic acid (NAM)- and N-acetylglucosamine (NAG)-peptide subunits into the peptidoglycan matrix; which forms the major structural component of Gram-positive cell walls.

The large hydrophilic molecule is able to form hydrogen bond interactions with the terminal D-alanyl-D-alanine moieties of the NAM/NAG-peptides. Normally this is a five-point interaction. This binding of vancomycin to the D-Ala-D-Ala prevents the incorporation of the NAM/NAG-peptide subunits into the peptidoglycan matrix.

Vancomycin exhibits atropisomerism — it has two chemically distinct rotamers owing to the rotational restriction of the chlorotyrosine residue (on the right hand side of the figure).

The form present in the drug is the thermodynamically more stable conformer, and, importantly, has more potent activity.

Clinical use

Indications

Vancomycin is indicated for the treatment of serious, life-threatening infections by Gram-positive bacteria which are unresponsive to other less toxic antibiotics.

The increasing emergence of vancomycin-resistant enterococci has resulted in the development of guidelines for use by the Centers for Disease Control (CDC) Hospital Infection Control Practices Advisory Committee. These guidelines restrict use of vancomycin to the following indications:[1]

- treatment of serious infections caused by susceptible organisms resistant to penicillins (methicillin-resistant Staphylococcus aureus and multi-resistant Staphylococcus epidermidis (MRSE)) or in individuals with serious allergy to penicillins
- pseudomembranous colitis (relapse or unresponsive to metronidazole treatment)
- For treatment of infections caused by gram-positive microorganisms in patients who have serious allergies to beta-lactam antimicrobials. (http://wonder.cdc.gov/wonder/prevguid/m0039349/m0039349.asp)
- antibacterial prophylaxis for endocarditis following certain procedures in penicillin-hypersensitive individuals at high risk
- surgical prophylaxis for major procedures involving implantation of prostheses in institutions with a high rate of MRSA or MRSE

Adverse effects

Common adverse drug reactions (e1% of patients) associated with IV vancomycin include: local pain, which may be severe and/or thrombophlebitis. Nephrotoxicity is an infrequent adverse effect (0.1–1% of patients). Rare adverse effects (<0.1% of patients) include: anaphylaxis, toxic epidermal necrolysis, erythema multiforme, red man syndrome (see below), superinfection, thrombocytopenia, neutropenia, leucopenia, tinnitus, dizziness and/or ototoxicity (see below).[1]

Dosing considerations

Intravenous vs oral administration

Vancomycin needs to be given intravenously (IV) for systemic therapy since it does not cross through the intestinal lining. It is a large hydrophilic molecule which partitions poorly across the gastrointestinal mucosa. The only indication for oral vancomycin therapy is in the

treatment of pseudomembranous colitis, where it must be given orally to reach the site of infection in the colon.

Red man syndrome

Vancomycin must be administered in a dilute solution slowly, over at least 60 minutes (maximum rate of 10 mg/minute for doses >500 mg).[1] This is due to the high incidence of pain and thrombophlebitis and to avoid an infusion reaction known as the *red man syndrome* or *red neck syndrome*. This syndrome, usually appearing within 4–10 minutes after the commencement or soon after the completion of an infusion, is characterised by flushing and/or and an erythematous rash that affects the face, neck and upper torso. Less frequently, hypotension and angioedema may also occur. Symptoms may be treated with antihistamines, including diphenhydramine.[2]

Therapeutic drug monitoring

Vancomycin activity is considered to be time-dependent – that is, antimicrobial activity depends on the duration that the drug level exceeds the minimum inhibitory concentration (MIC) of the target organism. Thus, peak levels have not been shown to correlate with efficacy or toxicity – indeed concentration monitoring is unnecessary in most cases. Circumstances where therapeutic drug monitoring (TDM) is warranted include: patients receiving concomitant aminoglycoside therapy, patients with (potentially) altered pharmacokinetic parameters, patients on haemodialysis, during high dose or prolonged treatment, and patients with impaired renal function. In such cases, trough concentrations are measured.[1][3][4][5]

Toxicity

Vancomycin has traditionally been considered a nephrotoxic and ototoxic drug, based on observations by early investigators of elevated serum levels in renally impaired patients who had experienced ototoxicity, and subsequently through case reports in the medical literature. However, as the use of vancomycin increased with the spread of MRSA beginning in the seventies, it was recognised that the previously reported rates of toxicity were not being observed. This was attributed to the removal of the impurities present in the earlier formulation of the drug, although those impurities were not specifically tested for toxicity.

Nephrotoxicity

Subsequent reviews of accumulated case reports of vancomycin-related nephrotoxicity found that many of the patients had also received other known nephrotoxins, particularly aminoglycosides. Most of the rest had other confounding factors, or insufficient data regarding the possibility of such, that prohibited the clear association of vancomycin with the observed renal dysfunction.

In 1994, Cantu and colleagues found that the use of vancomycin monotherapy was clearly documented in only three of 82 available cases in the literature.[3] Prospective and retrospective studies attempting to evaluate the incidence of vancomycin-related nephrotoxicity have largely been methodologically flawed and have produced variable results. The most methodologically sound investigations indicate that the actual incidence of vancomycin-induced nephrotoxicity is around 5–7%. To put this into context, similar rates of renal dysfunction have been reported for cefamandole and benzylpenicillin, two reputedly non-nephrotoxic antibiotics.

Additionally, evidence to relate nephrotoxicity to vancomycin serum levels is inconsistent. Some studies have indicated an increased rate of nephrotoxicity when trough levels exceed 10 µg/mL, but others have not reproduced these results. Nephrotoxicity has also been observed with concentrations within the "therapeutic" range as well. Essentially, the reputation of vancomycin as a nephrotoxin is over-stated, and it has not been demonstrated that maintaining vancomycin serum levels within certain ranges will prevent its nephrotoxic effects, when they do occur.

Ototoxicity

Attempts to establish rates of vancomycin-induced ototoxicity are even more difficult due to the scarcity of quality evidence. The current consensus is that clearly related cases of vancomycin ototoxicity are rare. The association between vancomycin serum levels and ototoxicity is also uncertain. While cases of ototoxicity have been reported in patients whose vancomycin serum level exceeded 80 µg/mL, cases have been reported in patients with therapeutic levels as well. Thus, it also remains unproven that therapeutic drug monitoring of vancomycin for the purpose of maintaining "therapeutic" levels will prevent ototoxicity.

Interactions with other nephrotoxins

Another area of controversy and uncertainty concerns the question of whether, and if so, to what extent, vancomycin increases the toxicity of other nephrotoxins. Clinical studies have yielded variable results, but animal models indicate that there probably is some increased nephrotoxic effect when vancomycin is added to nephrotoxins such as aminoglycosides. However, a dose- or serum level-effect relationship has not been established.

Antibiotic resistance

Microbial resistance to vancomycin is a growing problem, particularly within health care facilities such as hospitals. With vancomycin being the last-line antibiotic for serious Gram-positive infections there is the growing prospect that resistance will result in a return to the days when fatal bacterial infections were common. Vancomycin-resistant enterococci (VRE) emerged in 1987. Vancomycin-resistance emerged in more common pathogenic organisms during the 1990s and 2000s, including vancomycin-intermediate Staphylococcus aureus (VISA), vancomycin-resistant Staphylococcus aureus (VRSA), and vancomycin-resistant Clostridium difficile.[6][7] There is some suspicion that agricultural use of avoparcin,

another similar glycopeptide antibiotic, has contributed to the emergence of vancomycin-resistant organisms.

One mechanism of resistance to vancomycin appears to be alteration to the terminal amino acid residues of the NAM/NAG-peptide subunits, normally D-alanyl-D-alanine, which vancomycin binds to. Variations such as D-alanyl-D-lactate and D-alanyl-D-serine result in only a 4-point hydrogen bonding interaction being possible between vancomycin and the peptide. This loss of just one point of interaction results in a 1000-fold decrease in affinity.

In Enterococci this modification appears to be due to the expression of an enzyme which alters the terminal residue. Three main resistance variants have been characterised to date among resistant Enterococcus faecium and E. faecalis populations.

- VanA - resistance to vancomycin and teicoplanin, inducible on exposure to these agents
- VanB - lower level resistance, inducible by vancomycin but strains may remain susceptible to teicoplanin
- VanC - least clinically important, resistance only to vancomycin, constitutive resistance

The development and use of novel antibiotics such as linezolid and daptomycin is expected to delay, but not halt, the emergence of bacteria resistant to all available antibiotics.

Glycylcycline antibiotics

Glycylcyclines are a new class of antibiotics derived from tetracycline. These tetracycline analogues are specifically designed to overcome two common mechanisms of tetracycline resistance, namely resistance mediated by acquired efflux pumps and/or ribosomal protection. Presently, there is only one glycylcycline antibiotic for clinical use: tigecycline.

History

The development of these agents was spurred by the increasing prevalence of bacteria resistant to tetracyclines. These agents were first synthesized in the early 1990's by making modifications to the tetracyclines. By adding a bulky N,N-dimethylglycylamido side chain to position 9 of minocycline, the compound became less susceptible to tetracycline resistance mediated by acquired efflux pumps and/or ribosomal protection. Further development of this initial work led to the creation of tigecycline, the first glycylcycline available for clinical use.

Mechanism of Action

Glycylcycline antibiotics have a similar mechanism of action as tetracycline antibiotics. Both classes of antibiotics bind to the 30S ribosomal subunit to prevent the amino-acyl tRNA from binding to the A site of the ribosome. However, the glycylcyclines appear to bind more effectively than the tetracyclines [1].

Mechanisms of Resistance

While glycylcyclines have greater efficacy against organisms with tetracycline resistance mediated by acquired efflux pumps and/or ribosomal protection, the glycylcyclines are not effective against organisms with chromosomal efflux pumps, such as Pseudomonas and Proteeae [2].

Side Effects and Contraindications

Since glycylcyclines are similar to tetracyclines, they share many of the same side effects and contraindications as tetracyclines. These side effects may include nausea/vomiting, headache, photosensitivity, discoloration of growing teeth, and fetal damage.

These antibiotics should not be given to pregnant women due to risk of fetal harm. Additionally, these drugs should not be administered during periods of tooth development

because of the risk of tooth discoloration. Due to glycylcyclines' similarities with tetracyclines, hypersensitivity reactions to tetracycline antibiotics may predispose one to hypersensitivity reactions with glycylcycline antibiotics; hence, glycylcyclines should be used with caution in these patients.

Lincosamide antibiotics

Lincosamides (eg. lincomycin, clindamycin) are a class of drugs which bind to 50S subunit of bacterial ribosomes and inhibit early elongation of peptide chain by inhibiting transpeptidase reaction. In this sense they have a similar action to macrolides.

Resistance

Target bacteria may alter the drug's target site (similar to resistance found in macrolides and streptogramins). Also, enzymatic inactivation of clindamycin has been described (rare).

Pharmacodynamics

These are bacteriostatic drugs and antagonists of macrolides and streptogramins.

Nitroimidazole antibiotics

Nitroimidazoles are imidazole heterocycles with a nitro group that have been used to combat anaerobic bacterial and parasitic infections. Perhaps the most common example is metronidazole (*Flagyl* ®). Other heterocycles such as nitrothiazoles (thiazole) are also used for this purpose. Nitroheterocycles may be reductively activated in hypoxic cells, and then undergo redox recycling or decompose to toxic products.

Polyketide antibiotics

Polyketides are secondary metabolites from bacteria, fungi, plants, and animals. Secondary metabolites seem to be unnecessary for an organism's ontogeny, but appear to have applications such as defence and intercellular communication. Polyketides are derived from the polymerization of acetyl and propionyl subunits in a similar process to fatty acid synthesis. They also serve as building blocks for a broad range of natural products or are derivatized.

Polyketides are structurally a very diverse family of natural products with an extremely broad range of biological activities and pharmacological properties. Polyketide antibiotics, antifungals, cytostatics, anticholesterolemics, antiparasitics, coccidiostatics, animal growth promotants and natural insecticides are in commercial use.

Examples

- Macrolides
    - Picromycin, the first isolated macrolide (1950).
    - **The** antibiotics erythromycin B**,** clarithromycin**, and azithromycin.**
    - The immunosuppressant tacrolimus (FK506).
- **Polyene** antibiotics
    - Amphotericin.
- Tetracyclines
    - The tetracycline family of antibiotics.
- Others
    - Discodermolide

Biosynthesis

The biosynthesis of polyketides shares striking similarities with the fatty acid biosynthesis. Polyketides are synthesized by one or more specialized polyketide-synthase (PKS) enzyme. The PKS genes for a certain polyketide are usually organized in one operon in bacteria and in gene clusters in eukaryotes. The type I polyketide-synthases are large, highly modular proteins, while type II polyketide-synthases are aggregates of monofunctional proteins.

Each type I polyketide-synthase module consists of several domains with defined functions, separated by short spacer regions. The order of modules and domains of a complete polyketide-synthase is as follows (in the order N-terminus to C-terminus):

- Starting or loading module: AT-ACP-
- Elongation or extending modules: -KS-AT-[DH-ER-KR]-ACP-
- Termination or releasing module: -TE

Domains:

- AT: Acyl-transferase
- ACP: Acyl carrier protein with an SH group on the cofactor, a serine-attached 4'-Phosphopantetheine
- KS: Keto-synthase with an SH group on a cysteine side-chain
- KR: Keto-reductase
- DH: Dehydratase
- ER: Enoyl-reductase
- TE: Thio-esterase

The polyketide chain and the starter groups are bound with their carboxy group to the SH groups of the ACP and the KS domain through a thioester linkage: R-C(=O)OH + HS-protein <=> R-C(=O)S-protein + H2O. The growing chain is handed over from one SH group to the next by trans-acylations and is releases at the end by hydrolysis or by cyclization (alcoholysis or aminolysis).

Starting stage:

- The starter group, usually acetyl-CoA or malonyl-CoA, is loaded onto the ACP domain of the starter module catalyzed by the starter module's AT domain.

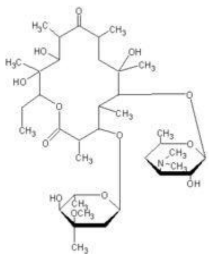
Elongation stages:

- The polyketide chain is handed over from the ACP domain of the previous module to the KS domain of the current module, catalyzed by the KS domain.
- The elongation group, usually malonyl-CoA or methyl-malonyl-CoA, is loaded onto the current ACP domain catalyzed by the current AT domain.
- The ACP-bound elongation group reacts in a Claisen condensation with the KS-bound polyketide chain under CO2 evolution, leaving a free KS domain and an ACP-bound elongated polyketide chain. The reaction takes place at the KS***n***-bound end of the chain, so that the chain moves out one position and the elangation group becomes the new bound group.
- Optionally, the new fragment of the polyketide chain can be altered stepwise by additional domains. The KR (keto-reductase) domain reduces the ^{2}-keto group to a ^{2}-hydroxy group, the DH (dehydratase) domain splits off H2O, resulting in the ±-^{2}-unsaturated alkene, and the ER (enoyl-reductase) domain reduces the ±-^{2}-double-bond to a single-bond.
- This cycle is repeated for each elongation module.

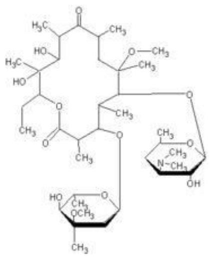
Termination stage:

- The TE (thio-esterase) domain hydrolyzes the completed polyketide chain from the ACP-domain of the previous module.

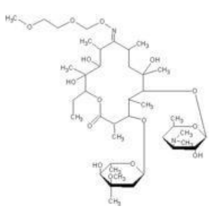
Macrolide antibiotics



Erythromycin. The macrolide ring is the lactone (cyclic ester) at upper left.



Clarithromycin



Roxithromycin

The *macrolides* are a group of drugs (typically antibiotics) whose activity stems from the presence of a macrolide ring, a large lactone ring to which one or more deoxy sugars, usually cladinose and desosamine, are attached. The lactone ring can be either 14, 15 or 16-membered. Macrolides belong to the polyketide class of natural products.

Members

Commonly prescribed Macrolides

- erythromycin
    - azithromycin (Zithromax®)
- clarithromycin **(Biaxin®)**
    - dirithromycin (Dynabac®)
    - roxithromycin (Rulid®, Surlid®)

Developmental Macrolides

- carbomycin A
josamycin

kitasamycin
oleandomycin
spiramycin
troleandomycin
tylosin/tylocine (Tylan®)

Ketolides

Ketolides are a new class of antibiotics that are structurally related to the macrolides. They are used to fight respiratory tract infections caused by macrolide-resistant bacteria.

- telithromycin (Ketek®)

cethromycin

Others are: spiramycin (used for treating toxoplasmosis), ansamycin, oleandomycin, carbomycin and tylocine.

Non-antibiotic macrolides

The drug Tacrolimus, which is used as an immunosuppressant, is also a macrolide. It has similar activity to cyclosporin.

Toxic macrolide

- mycolactone

Uses

Macrolides are used to treat infections such as respiratory tract infections and soft tissue infections. The antimicrobial spectrum of macrolides is slightly wider than that of penicillin, and therefore macrolides are a common substitute for patients with a penicillin allergy. Beta-hemolytic streptococci, pneumococci, staphylococci and enterococci are usually susceptible to macrolides. Unlike penicillin, macrolides have been shown to be effective against mycoplasma, mycobacteria, some rickettsia and chlamydia.

Mechanism of action

The mechanism of action of the macrolides is inhibition of bacterial protein synthesis by binding reversibly to the subunit 50S of the bacterial ribosome, thereby inhibiting translocation of peptidyl-tRNA. This action is mainly bacteriostatic, but can also be bactericidal in high concentrations. Macrolides tend to accumulate within leukocytes, and are therefore actually transported into the site of infection.

- A novel, non-antibiotic, anti-inflammatory effect of 14-membered macrolides was discovered in Japan(Kudo S. et al.), which is especially effective in improving control of diffuse panbronchiolitis(DPB). Research on the anti-inflammatory properties of the macrolide ring is ongoing.

Resistance

The primary means of bacterial resistance to macrolides occurs by post-transcriptional methylation of the of the 23S bacterial ribosome. This acquired resistance can be either plasmid-mediated or chromosomal, i.e through mutation, and results in cross-resistance to macrolides, lincosamides, and streptogramins (an MLS-resistant phenotype).

Two other types of acquired resistance rarely seen include the production of drug-inactivating enzymes (esterases or kinases) as well as the production of active ATP-dependent efflux proteins that transport the drug outside of the cell.

Routes oral

Clarithromycin is a macrolide antibiotic used to treat pharyngitis, tonsillitis, acute maxillary sinusitis, acute bacterial exacerbation of chronic bronchitis, pneumonia (especially atypical pneumonias associated with Chlamydia pneumoniae or TWAR), skin and skin structure infections, and, in HIV and AIDS patients to prevent, and to treat, disseminated Mycobacterium avium complex or MAC. In addition, it is sometimes used to treat Legionellosis.

Clarithromycin is available under several brand names, for example *Biaxin*, *Klacid*, and *Claripen*.

History

Clarithromycin was invented by scientists at the Japanese drug company Taisho Pharmaceutical in the 1970s. The product had emerged through efforts to develop a version of the antibiotic erythromycin that did not experience acid instability in the digestive tract and thereby cause side effects, such as nausea and stomach ache. Taisho filed for patent protection over its new drug around 1980 and subsequently introduced a branded version of its drug, called Clarith, to the Japanese market in 1991. In 1985 Taisho had partnered with the American company Abbott Laboratories for the international rights, and Abbott also gained FDA approval for Biaxin in October 1991. The drug went generic in Europe in 2004 and in the U.S. in mid-2005.

Potential new uses

The Australian biotechnology company Giaconda is working on a new triple drug therapy for Crohn's disease that combines clarithromycin with rifabutin and clofazimine.

Available forms

Clarithromycin is commonly administered in tablets (Biaxin®), extended-release tablets (Biaxin XL®), or oral suspension. In the United States generic clarithromycin is available from Andrx, Genpharm, Ivax, Ranbaxy Laboratories, Roxane, Sandoz, Teva and Wockhardt.

Mechanism of action

Clarithromycin prevents bacteria from growing, by interfering with their protein synthesis. Clarithromycin binds to the subunit 50S of the bacterial ribosome, and thus inhibits the translocation of peptides. Clarithromycin has similar antimicrobial spectrum as erythromycin, but is more effective against certain gram-negative bacteria, particularly Legionella pneumophilae. Besides this bacteriostatic effect, clarithromycin also has bactericidal effect on certain strains such as Haemophilus influenzae, Streptococcus pneumoniae and Neisseria gonorrhoeae.

Pharmacokinetics

Unlike erythromycin, clarithromycin is acid-stable and can therefore be taken orally without being protected from gastric acids. It is readily absorbed, and diffused into most tissues and phagocytes. Due to the high concentration in phagocytes, clarithromycin is actively transported to the site of infection. During active phagocytosis, large concentrations of clarithromycin is released. The concentration of clarithromycin in the tissues can be over 10 times higher than in plasma. Highest concentrations were found in liver and lung tissue.

Metabolism

Clarithromycin has a fairly rapid first-pass hepatic metabolism, i.e it is metabolised by the liver. However, this metabolite, 14-hydroxy clarithromycin is almost twice as active as clarithromycin. The half-life of clarithromycin is about 5 hours and 14-hydroxy clarithromycin's about 7 hours. Clarithromycin's and its metabolites' main routes of elimination are urinary and biliary excretion.

Side effects

Most common side-effects are gastrointestinal: diarrhea, nausea, abdominal pain and vomiting. Less common side-effects include headaches, rashes, alteration in senses of smell and taste. Dry mouth, anxiety, hallucinations, and nightmares have also been reported. In more serious cases it has been known to cause jaundice, other liver disorders, and kidney problems including kidney failure. Inform your doctor immediately if side effects are extremely bothersome or serious.

Special precautions

Allergic reactions can occur with clarithromycin use. People with a history of allergy, asthma, hay fever or hives seem to be more susceptible to these reactions. The reaction can be immediate and severe.

Allergic symptoms include wheezing, hives, itching, swelling, spasms in the throat and breathing tubes, swelling of the face and neck, joint and muscle pain, difficulty breathing, fever and skin rashes. Rashes can range in severity, the most serious cases being toxic

epidermal necrolysis and Stevens-Johnson syndrome. Nausea and vomiting are not symptoms of an allergic reaction.

Contraindications

Clarithromycin should be used with caution if the patient has liver or kidney disease, certain heart problems (e.g., QTc prolongation or bradycardia), or a mineral imbalance (e.g., low potassium or magnesium levels). Many drugs interact with clarithromycin: be sure to carefully read the information sheet to make sure you are not currently taking one that might adversely react.

Routes oral, iv, im

Erythromycin (also known as *eryth ethylsuc*) is a macrolide antibiotic which has an antimicrobial spectrum similar to or slightly wider than that of penicillin, and is often used for people who have an allergy to penicillins. For respiratory tract infections, it has better coverage of atypical organisms, including mycoplasma. It is also used to treat outbreaks of chlamydia, syphilis, acne and gonorrhea. Structurally, this macrocyclic compound contains a 14-membered lactone ring with ten asymmetric centers and two sugars (L-cladinose and D-desoamine), making it a compound very difficult to produce via synthetic methods.

Erythromycin is produced from a strain of the actinomyces Saccaropolyspora erythraea, formerly known as Streptomyces erythraeus.

History

Abelardo Aguilar, a Filipino scientist, sent some soil samples to his employer Eli Lilly in 1949. Eli Lilly's research team, led by J. M. McGuire, managed to isolate Erythromycin from the metabolic products of a strain of Streptomyces erythreus (designation changed to "Saccharopolyspora erythraea") found in the samples. Lilly filed for patent protection of the compound and U.S. patent 2,653,899 was granted in 1953. The product was launched commercially in 1952 under the brand name *Ilosone*® (after the Philippine region of Iloilo where it was originally collected from). Erythromycin was formerly also called *Ilotycin*®. In 1981, Nobel laurate (1965 in chemistry) and Professor of Chemistry at Harvard University (Cambridge, MA) Robert B. Woodward and a large team of researchers reported the first stereocontrolled asymmetric chemical synthesis of Erythromycin A.

The antiobiotic clarithromycin was invented by scientists at the Japanese drug company Taisho Pharmaceutical in the 1970s as a result of their efforts to overcome the acid instability of erythromycin.

Available forms

Erythromycin is available in enteric-coated tablets, slow release capsules, oral suspensions, ophthalmic solutions, ointments, gels and injections.

Brand names include Robimycin, E-Mycin, E.E.S. Granules, E.E.S.-200, E.E.S.-400, E.E.S.-400 Filmtab, Erymax, Ery-Tab, Eryc, Erypar, EryPed, Eryped 200, Eryped 400, Erythrocin Stearate Filmtab, Erythrocot, E-Base, Ilosone, MY-E, Pediamycin, Zineryt and PCE Dispertab.

Mechanism of action

Erythromycin prevents bacteria from growing by interfering with their protein synthesis. Erythromycin binds to the 23s rRNA molecule in the 50S of the bacterial ribosome, blocking the exit of the growing peptide chain thus inhibiting the translocation of peptides.

Pharmacokinetics

Erythromycin is easily inactivated by gastric acids, therefore all orally administered formulations are given as either enteric coated or as more stable salts or esters. Erythromycin is very rapidly absorbed, and diffused into most tissues and phagocytes. Due to the high concentration in phagocytes, erythromycin is actively transported to the site of infection, where during active phagocytosis, large concentrations of erythromycin are released.

Metabolism

Most of erythromycin is metabolised by demethylation in the liver. Its main elimination route is in the bile, and a small portion in the urine. Erythromycin's half-life is 1.5 hours.

Side-effects

Gastrointestinal disturbances such as diarrhea, nausea, abdominal pain and vomiting are fairly common so it tends not to be prescribed as a first-line drug. However, erythromycin may be useful in treating gastroparesis due to this pro-motility effect. Intravenous erythromycin may also be used in endoscopy as an adjunct to clear gastric contents.

More serious side-effects, such as reversible deafness are rare. Allergic reactions, while uncommon, may occur, ranging from urticaria to anaphylaxis. Cholestasis, Stevens-Johnson syndrome and toxic epidermal necrolysis are some other rare side effects that may occur.

Erythromycin has been shown to increase the probability of pyloric stenosis in children whose mothers took the drug during the late stages of pregnancy or while nursing.

Contraindications

Earlier case reports on sudden death prompted a study on a large cohort that confirmed a link between erythromycin, ventricular tachycardia and sudden cardiac death in patients also taking drugs that prolong the metabolism of erythromycin (like verapamil or diltiazem) by interfering with CYP3A4 (Ray et al 2004). Hence, erythromycin should not be administered in patients using these drugs, or drugs that also prolong the QT time. Other examples include terfenadine (Seldane, Seldane-D), astemizole (Hismanal), cisapride (Propulsid, withdrawn in many countries for prolonging the QT time) and pimozide (Orap).

Some people can be allergic to Erythromycin and a small dose can cause massive liver failure.

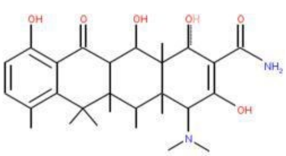
Tetracycline antibiotics



The 4 rings of the basic tetracycline structure.

Tetracyclines are a group of broad-spectrum antibiotics whose general usefulness has been reduced with the onset of bacterial resistance. Despite this, they continue to remain the treatment of choice for some specific indications.

They are so named for their four (“tetra-”) hydrocarbon rings (“-cycl-”) derivation (“-ine”).

History

The first member of the group to be discovered was Chlortetracycline (Aureomycin) in the late 1940s by Dr. Benjamin Duggar, a scientist employed by Lederle Laboratories who derived the substance from a golden-colored, fungus-like, soil-dwelling bacterium named Streptomyces aureofaciens. Oxytetracycline (Terramycin) was discovered shortly afterwards by AC Finlay et al, it came from a similar soil bacterium named Streptomyces rimosus. Robert Burns Woodward determined the structure of Oxytetracycline enabling Lloyd H. Conover to successfully produce tetracycline itself as a synthetic product. The

development of many chemically altered antibiotics formed this group. In June 2005, tigecycline, the first member of a new subgroup of tetracyclines named glycylcyclines was introduced to treat infections which are resistant to other antimicrobics including conventional Tetracyclines.

Examples of tetracyclines

- Naturally-occurring
  - Tetracycline
  - Chlortetracycline
  - Oxytetracycline
  - Demeclocycline
- Semi-synthetic
  - Doxycycline
  - Lymecycline
  - Meclocycline
  - Methacycline
  - Minocycline
  - Rolitetracycline

Tigecycline may also be considered a tetracycline antibiotic, though it is usually classified as a glycylcycline antibiotic.

Indication

Tetracyclines may be used in the treatment of infections of the respiratory tract, sinuses, middle ear, urinary tract, intestines, and also gonorrhoea, especially in patients allergic to ^{2}-lactams and macrolides; however, their use for these indications is less popular than it once was due to widespread resistance development in the causative organisms.

Their most common current use is in the treatment of moderately severe acne and rosacea (tetracycline, oxytetracycline, doxycycline or minocycline).

Doxycycline is also used as a prophylactic treatment for infection by Bacillus anthracis (anthrax) and is effective against Yersinia pestis, the infectious agent of bubonic plague. It is also used for malaria treatment and prophylaxis, as well as treating elephantiasis.

They remain the treatment of choice for infections caused by chlamydia (trachoma, psittacosis, salpingitis, urethritis and L. venereum infection), Rickettsia (typhus, Rocky Mountain spotted fever), brucellosis, and spirochetal infections (borreliosis, syphilis, and Lyme disease). In addition, they may be used to treat anthrax, plague, tularemia, and Legionnaires' disease.

They may have a role in reducing the duration and severity of cholera, although drug-resistance is occurring[1] and their effects on overall mortality is questioned.[2]

Demeclocycline has an additional use in the treatment of SIADH.

Tetracycline derivatives are currently being investigated for the treatment of certain inflammatory disorders.

Administration

When ingested, it is usually recommended that tetracyclines should be taken with a full glass of water two hours after eating, and one hour before eating. This is partly due to the fact that tetracycline binds easily with magnesium, aluminium, iron, and calcium, which reduces its ability to be completely absorbed by the body. Dairy products or preparations containing iron are not recommended directly after taking the drug.

Cautions

Tetracyclines should be used with caution in those with liver impairment and may worsen renal failure (except doxycycline and minocycline). They may increase muscle weakness in myasthenia gravis and exacerbate systemic lupus erythematosus. Antacids and milk reduce the absoption of tetracyclines.

Like many antibiotics, they decrease the effectiveness of birth control pills.

Drugs in the tetracycline class become toxic over time, so expired prescriptions of these drugs should be discarded after the expiration date has passed.

Contraindications

Tetracycline use should be avoided in pregnant or lactating women, and in children with developing teeth because they may result in permanent staining (dark yellow-gray teeth with a darker horizontal band that goes across the top and bottom rows of teeth), and possibly affect the growth, of teeth and bones.

Side effects

Side effects from tetracyclines are not always common, but of particular note is possible photosensitive allergic reaction which increases the risk of sunburn under exposure to UV light from the sun or other sources. This may be of particular importance for those intending to take on holidays long-term doxycyline as a malaria prophylaxis.

They may cause stomach or bowel upsets, and rarely allergic reactions. Very rarely severe headache and vision problems may be signs of dangerous secondary intracranial hypertension also known as Pseudotumor cerebri.

Mechanism and resistance

Tetracycline inhibits cell growth by inhibiting translation. It binds to the 16S part of the 30S ribosomal subunit and prevents the amino-acyl tRNA from binding to the A site of the ribosome. The binding is reversible in nature.

Cells become resistant to tetracycline by at least three mechanisms: enzymatic inactivation of tetracycline, efflux and ribosomal protection. Inactivation is the rarest type of

resistance, where an acetyl group is added to the molecule, causing inactivation of the drug. In efflux, a resistance gene encodes a membrane protein that actively pumps tetracycline out of the cell. This is the mechanism of action of the tetracycline resistance gene on the artificial plasmid pBR322. In Ribosomal protection a resistance gene encodes a protein which can have several effects depending on what gene is transferred. Six classes of ribosomal protection genes/proteins have been found, all with high sequence homology suggesting a common evolutionary ancestor. Possible mechanisms of action of these protective proteins include: 1) blocking tetracyclines from binding to the ribosome, 2) binding to the ribosome and distorting the structure to still allow t-RNA binding while tetracycline is bound, and 3) binding to the ribosome and disloding tetracycline. All of these changes to ribosomes are reversible (non-covalent) because ribosomes isolated from both tetracycline resistant and susceptible organisms both bind tetracycline equally well in vitro.

Doxycycline (INN) (IPA: [ÌdRksjÈsajklin]) is a member of the tetracycline antibiotics group and is commonly used to treat a variety of infections. Brand names include Monodox®, Periostat®, Vibramycin®, Vibra-Tabs®, Doryx®, Vibrox®, Adoxa®, Doxyhexal® and Atridox® (topical doxycycline hyclate for gum disease).

Indicated uses

As well as the general indications for all members of the tetracycline antibiotics group, Doxycycline is frequently used to treat chronic prostatitis, sinusitis, syphilis, chlamydia, pelvic inflammatory disease, acne and rosacea. In addition it is used in the treatment and prophylaxis of Bacillus anthracis (anthrax) and malaria. Its mechanism of action against malaria is to specifically impair in the progeny the apicoplast genes resulting in their abnormal cell division.[1]

It is also effective against Yersinia pestis (the infectious agent of bubonic plague) and is prescribed for the treatment of Lyme disease and Rocky Mountain spotted fever.

Elephantiasis is a disease caused by a nematode (worm) Wuchereria bancrofti. It causes swollen limbs and genitals (Filariasis) and affects over 120 million people in the world. Previous anti-nematode treatments have been limited by poor levels of effectiveness, drug side effects and high costs. Doxycycyline was shown in 2003 to kill the symbiotic Wolbachia bacteria upon which the nematodes are dependent.[2] Field trials in 2005 showed that

Doxycycline almost completely eliminates blood-borne filaria when given for an 8 week course.[3][4]

Cautions and Side effects

Are as for other members of the tetracycline antibiotics group. However the 10% risk of photosensitivity skin reactions is of particular importance for those intending long-term use for malaria prophylaxis. Reports of GERD have been cited with the use of Doxycycline.

Unlike some other members of the group, it may be used in those with renal impairment.

Doxycycline impairs the effectiveness of many types of contraceptive pill and physicians recommend the use of barrier contraception for people taking the drug to prevent unwanted pregnancy. Contrary to popular belief, the drug does not cause patients to exhibit side-effects preventing other forms of sexual activity such as oral or anal sex.

It should be taken with a full glass of water to prevent irritation of the esophagus or stomach.

Experimental applications

At subantimicrobial doses, doxycycline is an inhibitor of matrix metalloproteinases, and has been used in various experimental systems for this purpose. Doxycycline has been used successfully in the treatment of one patient with lymphangioleiomyomatosis, an otherwise progressive and fatal disease.[5]

Doxycycline has also been used to regulate transgene expression in mice using the Tet-on gene control system.

Tetracycline (INN) (IPA: [Ìt[trYÈsajklin]) is a broad-spectrum antibiotic produced by the streptomyces bacterium, indicated for use against many bacterial infections. It is commonly used to treat acne. It is sold under the brand names *Sumycin®;*, *Tetracyn®;* and *Panmycin®*, among others. *Actisite®* is a thread-like fiber form, used in dental applications. It is also used to produce several semi-synthetic derivatives, which together are known as the Tetracycline antibiotic group. It works by inhibiting action of the prokaryotic 30S ribosome. Toxicity may be result of inactivation of mitochondrial 30S ribosomes in host cells.

History

Tetracycline was first discovered by Lloyd Conover in the research departments of Pfizer. The patent for Tetracycline was first issued in 1950 (patent number 2,624,354). Tetracycline sparked the development of many chemically altered antibiotics and in doing so has proved to be one of the most important discoveries made in the field of antibiotics.

Cautions, Contraindications, Side effects

Are as those of the Tetracycline antibiotics group:

- Can stain developing teeth (even when taken by the mother during pregnancy)

Inactivated by Ca^{2+} ion, not advised to be taken with milk or yogurt
Skin photosensitivity, not advised to be exposed to the Sun or intense light
Drug induced lupus, and hepatitis
Tinnitus

Indication

Tetracycline's primary use is for the treatment of acne vulgaris and rosacea.

It is also used to treat a very wide range of infections; see Tetracycline antibiotics for details.

Other uses

Since tetracycline is absorbed into bone, it is used as a marker of bone growth for biopsies in humans, and as a biomarker in wildlife to detect consumption of medicine- or vaccine-containing baits. The presence of tetracyline in bone is detected by its fluorescence.

Polymyxin antibiotics

Polymyxins are cationic detergent antibiotics, with a general structure of a cyclic peptide with a long hydrophobic tail. They disrupt the structure of the bacterial cell membrane by interacting with its phospholipids. Polymyxins have a bactericidal effect on Gram-negative bacilli, especially on pseudomonas and coliform organisms. Polymyxin antibiotics are highly neurotoxic and nephrotoxic, and very poorly absorbed from the gastrointestinal tract.

Well known examples:

- Colistin
Polymyxin B
Surfactin

Polymyxin acts as an antibiotic by damaging the cytoplasmic membrane of bacteria. Also polymyxins biological source is Bacillius polymyxa.

Polypeptide antibiotics - Lantibiotics

Lantibiotics are a class of peptide antibiotics that contain polycyclic thioether amino acids as well as the unsaturated amino acids dehydroalanine and 2-aminoisobutyric acid. These characteristic cyclic thioether amino acids are composed of either lanthionine or methyllanthionine. Lantibiotics are produced by a large number of Gram positive bacteria such as Streptococcus and Streptomyces to attack other gram positive bacteria and as such they are considered a member of the bacteriocins.

History

[1]The name Lantibiotics was introduced in 1988 as an abbreviation for "Lanthionine-containing peptide antibiotics". The first structures of these antimicrobial agents were first produced by pioneering work by Gross and Morell in the late sixties and early seventies, thus marking the formal intorduction of Lantibiotics. Since then Lantibiotics such as Nisin have been used auspiciously for food preservation and have yet to encounter significant bacterial

resistance. These attributes of lantibiotics have lead to more detailed research into their structures and biosynthetic pathways.

Classification

- Type A Lantibiotics are long flexible molecules - eg Nisin, subtilin, epidermin. Subgroup AI includes Mutacin II, subgroup AII includes Mutacin I & III.
- Type B Lantibiotics are globular - eg mersacidin, actagardin, cinnamycin.

See Brotz and Sahl. JAC (2000) 46, 1-6 for discussion of mechanism of action. (Type A kill rapidly by pore formation, type B inhibit peptidoglycan biosynthesis)

Mechanism of action

Lantibiotics show substantial specificity for some components (eg lipid II) of bacterial cell membranes especially of Gram positive bacteria. They are active in very low concentrations.

Application

[2]Lantibiotics are produced by Gram-positive bacteria and show strong antimicrobial action towards a wide range of other Gram-positive bacteria. As such they have become attractive candidates for use in food preservation (by inhibiting pathogens that cause food spoilage) and the pharmaceutical industry (to prevent or fight infections in humans or animals). See C. van Kraaij et al, Nat. Prod. Rep. (1999), 16, 583 - 584 for more detailed disccusion of the pharmaceutical application of lantibiotics.

Rifamycin antibiotics

The *rifamycins* are a group of antibiotics which are synthesized either naturally by the bacterium Amycolatopsis mediterranei, or artificially. Rifamycins are particularly effective against mycobacteria, and are therefore used to treat tuberculosis, leprosy, and mycobacterium avium complex (MAC) infections.

The rifamycin group includes the "classic" rifamycin drugs as well as the rifamycin derivatives Rifampicin, Rifabutin and Rifapentine.

The bacterium

Streptomyces mediterranei was first isolated in 1957 from a soil sample collected near the beachside town of St Raphael in southern France. The name was originally given by two microbiologists working with the Italian drug company Group Lepetit SpA in Milan, the Italian Grazia Beretta and Pinhas Margalith of Israel.

In 1969 the bacterium was renamed Nocardia mediterranei when another scientist named Thiemann found that it had a cell wall typical of the Nocardia species. Then in 1986 the bacterium was renamed again as Amycolatopsis mediterranei, as the first species of a new genus, because a scientist named Lechevalier discovered that the cell wall lacked mycolic acid and was not able to be infected by the Nocardia and Rhodococcus phages.

The classic rifamycin drugs

Rifamycins were first isolated in 1957 from a fermentation culture of Streptomyces mediterranei at the laboratory of Gruppo Lepetit SpA in Milan by a scientist named Piero Sensi, working with the Israeli scientist Pinhas Margalith. Eventually around seven rifamycins were discovered, named Rifamycin A, B, C, D, E, S and SV.

Of the various rifamycins Rifamycin B was first introduced commercially. Lepetit filed for patent protection of Rifamycin B in the UK in August 1958 and in the US in March 1959. The British patent GB921045 was granted in March 1963 and U.S. Patent 3,150,046 was granted in September 1964. The drug is widely regarded as having helped conquer the issue of drug-resistant tuberculosis in the 1960s.

The rifamycin derivatives

Lepetit introduced Rifampicin, an orally active rifamycin, around 1966. Rifabutin, a derivative of rifamycin S, was invented around 1975 and came on to the US market in 1993. Hoechst Marion Roussel (now part of Aventis) introduced rifapentine in 1999.

Rifaximin is a oral rifamycin marketed in the US by Salix Pharmaceuticals that is not absorbed from the intestine. It is intended to treat intestinal infections due to Escherichia coli.

Currently available rifamycins

- Rifampicin
Rifabutin
Rifapentine
Rifaximin

Formula C***6***H***8***N***2***O***2***S

Mol. weight 172.206 g/mol

There are several *sulphonamide*-based groups of drugs. The original *antibacterial sulfonamides* (sometimes called simply *sulfa drugs*) are synthetic antimicrobial agents that contain the sulfonamide group. The *sulfonylureas* (main article: sulfonylureas) and *thiazide diuretics* (main article thiazide) are newer drug groups based on the antibacterial sulfonamides.

In bacteria, antibacterial sulfonamides act as competitive inhibitors of the enzyme dihydropteroate synthetase, DHPS. DHPS catalyses the coversion of PABA (para-aminobenzoate) to dihydropteroate, a key step in folate synthesis. Folate is necessary for the cell to synthesize nucleic acids (nucleic acids are essential building blocks of DNA and RNA), and in its absence cells will be unable to divide. Hence the sulfonamide antibacterials exhibit a bacteriostatic rather than bactericidal effect.

Folate is not synthesized in mammalian cells, but is instead a dietary requirement. This explains the selective toxicity to bacterial cells of these drugs.

Sulfa allergies are common, hence medications containing sulfonamides are prescribed carefully.

History

Sulfonamide drugs (known widely as "sulfa drugs") were the first antibacterial antibiotics, and paved the way for the antibiotic revolution in medicine. The first sulfonamide was trade named Prontosil, which is a prodrug. Experiments with Prontosil began in 1932 in the laboratories of the Bayer Corporation, a component of the huge German chemical trust IF Farben. The dye-based drug was synthesized by Bayer chemist Josef Klarer and tested in animals under the direction of physician/researcher Gerhard Domagk. Domagk quickly won the 1939 Nobel Prize in Medicine and Physiology, an honor that Hitler forbade him to accept (Hitler was incensed at the awarding of a Nobel Peace Prize a few years earlier to an anti-Nazi activist). Domagk's Prize also caused some bad feeling between him and Klarer. The discovery was in fact a team effort in which Domagk played a central role, operating under the general direction of Heinrich Hoerlein, a Farben executive later tried (and acquited) at Nuremberg. The first official communication about the breakthrough discovery was not published until 1935, more than two years after the drug was patented by Klarer and his research partner Fritz Mietzsch. Prontosil was the first medicine ever discovered that could effectively treat a range of bacterial infections inside the body. It had a strong protective action against infections caused by streptococci, including blood infections, childbed fever, and erysipelas, and a lesser effect on infections caused by other cocci. Perplexingly, it had no effect at all in the test tube, exerting its antibacterial action only in live animals. Later it was discovered by a French research team at the Pasteur Institute that the drug was metabolized into two pieces inside the body, releasing from the inactive dye portion a smaller, colorless, active compound called sulfanilamide. The discovery helped establish the concept of "bioactivation" and dashed the German corporation's dreams of enormous profit; the active molecule sulfanilamide (or sulfa) had first been synthesized in 1906 and was widely used in the dye-making industry; its patent had since expired and the drug was available to anyone.

The result was a sulfa craze. For several years in the late 1930s hundreds of manufacturers produced tens of thousands of tons of myriad forms of sulfa. Unfortunately one of them, a preparation called Elixir Sulfanilamide, was made with a toxic solvent, diethylene glycol. The Elixir killed more than one hundred people, mostly children, in the US, and led to the passage of the 1938 Food, Drug, and Cosmetic Act. As the first and only only effective antibiotic available in the years before penicillin, sulfa drugs continued to thrive through the early years of World War II, saving the lives of Winston Churchill, Franklin Delano Roosevelt's son, and tens of thousands of patients. Sulfa had a central role in preventing wound infections during the war. American soldiers were issued a first aid kit containing sulfa powder and were told to sprinkle it on any open wound. During the years 1942 to 1943, Nazi doctors conducted sulfanilamide experiments on prisoners in concentration camps.

The sulfanilamide compound is more active in the protonated form, which in case of the acid works better in a basic environment. The solubility of the drug is very low and sometimes can crystalize in the kidneys, due to its first pK***a*** of around 10. This is a very painful experience so patients are told to take the medication with copious amounts of water. Newer compounds have a pK***a*** of around 5-6 so the problem is avoided.

Many thousands of molecules containing the sulfanilamide structure have been created since its discovery (by one account, over 5400 permutations by 1945), yielding improved formulations with greater effectiveness and less toxicity. Sulfa drugs are still widely used for

conditions such as acne and urinary tract infections, and are receiving renewed interest for the treatment of infections caused by bacteria resistant to other antibiotics.

Sulpha is an alternate (UK English) spelling of the common name for Sulfonamide antibiotics.

Preparation

Sulfonamides are prepared by the reaction of a sulfonyl chloride with ammonia or an amine. Certain sulfonamides (sulfadiazine or sulfamethoxazole) are sometimes mixed with the drug trimethoprim, which acts against dihydrofolate reductase.

Side Effects

Sulfonamides have the potential to cause a variety of untoward reactions, including urinary tract disorders, haemopoietic disorders, porphyria and hypersensitivity reactions. When used in large dose, it may develop a strong allergic reaction.

- Antibiotic

Antibiotic resistance

Antibiotic resistance is the ability of a microorganism to withstand the effects of an antibiotic. Antibiotic resistance can develop naturally via natural selection through random mutation. SOS response of low-fidelity polymerases can also cause mutation via a process known as programmed evolution. Once such a gene is generated, bacteria can then transfer the genetic information in a horizontal fashion (between individuals) by plasmid exchange. If a bacterium carries several resistance genes, it is called *multiresistant* or, informally, a *superbug*.

Antibiotic resistance can also be introduced artificially into a microorganism through transformation protocols. This can be a useful way of implanting artificial genes into the microorganism.

Causes

Antibiotic resistance is a consequence of evolution via natural selection or programmed evolution. The antibiotic action is an environmental pressure; those bacteria which have a mutation allowing them to survive will live on to reproduce. They will then pass this trait to their offspring, which will be a fully resistant generation.

Several studies have demonstrated that patterns of antibiotic usage greatly affect the number of resistant organisms which develop. Overuse of broad-spectrum antibiotics, such as second- and third-generation cephalosporins, greatly hastens the development of methicillin resistance, even in organisms that have never been exposed to the selective pressure of methicillin per se (thus the resistance was already present). Other factors contributing towards resistance include incorrect diagnosis, unnecessary prescriptions, improper use of antibiotics by patients, and the use of antibiotics as livestock food additives for growth promotion.

Mechanisms of antibiotic resistance

The four main mechanisms by which microorganisms exhibit resistance to antimicrobials are:

1. Drug inactivation or modification: e.g. enzymatic deactivation of Penicillin G in some penicillin-resistant bacteria through the production of ^{2}-lactamases.
2. Alteration of target site : e.g. alteration of PBP - the binding target site of penicillins - in MRSA and other penicillin-resistant bacteria.

3. Alteration of metabolic pathway: e.g. some sulfonamide-resistant bacteria do not require para-aminobenzoic acid (PABA) - an important precursor for the synthesis of folic acid and nucleic acids in bacteria inhibited by sulfonamides. Instead, like mammalian cells, they turn to utilizing preformed folic acid.
4. Reduced drug accumulation: by decreasing drug permeability and/or increasing active efflux on the cell surface.

Resistant pathogens

Staphylococcus aureus (colloquially known as "Staph aureus") is one of the major resistant pathogens. Found on the mucous membranes and the skin of around a third of the population, it is extremely adaptable to antibiotic pressure. It was the first bacterium in which penicillin resistance was found -- in 1947, just four years after the drug started being mass-produced. Methicillin was then the antibiotic of choice. MRSA (methicillin-resistant Staphylococcus aureus) was first detected in Britain in 1961 and is now "quite common" in hospitals. MRSA was responsible for 37% of fatal cases of blood poisoning in the UK in 1999, up from 4% in 1991. Half of all S. aureus infections in the US are resistant to penicillin, methicillin, tetracycline and erythromycin.

This left vancomycin as the only effective agent available at the time. However, VRSA (Vancomycin-resistant Staphylococcus aureus) was first identified in Japan in 1997, and has since been found in hospitals in England, France and the US. VRSA is also termed GISA (glycopeptide intermediate Staphylococcus aureus) or VISA (vancomycin insensitive Staphylococcus aureus), indicating resistance to all glycopeptide antibiotics.

A new class of antibiotics, oxazolidinones, became available in the 1990s, and the first commercially available oxazolidinone, linezolid, is comparable to vancomycin in effectiveness against MRSA. Linezolid-resistance in Staphylococcus aureus was reported in 2003.

Enterococcus faecium is another superbug found in hospitals. Penicillin-Resistant Enterococcus was seen in 1983, Vancomycin-Resistant Enterococcus (VRE) in 1987, and Linezolid-Resistant Enterococcus (LRE) in the late 1990s.

Penicillin-resistant pneumonia (or pneumococcus, caused by Streptococcus pneumoniae) was first detected in 1967, as was penicillin-resistant gonorrhea. Resistance to penicillin substitutes is also known as beyond S. aureus. By 1993 Escherichia coli was resistant to five fluoroquinolone variants. Mycobacterium tuberculosis is commonly resistant to isoniazid and rifampin and sometimes universally resistant to the common treatments. Other pathogens showing some resistance include Salmonella, Campylobacter, and Streptococci.

In November, 2004, the Centers for Disease Control and Prevention (CDC) reported an increasing number of Acinetobacter baumannii bloodstream infections in patients at military medical facilities in which service members injured in the Iraq/Kuwait region during Operation Iraqi Freedom and in Afghanistan during Operation Enduring Freedom were treated. Most of these showed multidrug resistance (MRAB), with a few isolates resistant to all drugs tested. [1]

Antibiotic resistance and the role of animals

MRSA is acknowledged to be a human commensal and pathogen. MRSA has been found in cats, dogs and horses, where it can cause the same problems as it does in humans. Owners can transfer the organism to their pets and vice-versa, and MRSA in animals is generally believed to be derived from humans.

This is not the case for other pathogens, however. There are concerns that some antibiotic resistant organisms may derive from the use of antibiotics in food animals. 15% of all antibiotics manufactured in Europe are used on animals. For precisely this reason, in many countries, antibiotics that are licensed for human use are banned from use in animals. However, related antibiotics are often used as growth promoters and to prevent or treat illnesses (particularly in poultry) and have been associated with the development of resistant strains in bacteria isolated from poultry and other food animals.

The US Food and Drug Administration banned enrofloxacin from use in poultry in July 2005 in response to concerns that use of enrofloxacin use in chickens might contribute to ciprofloxacin resistance in Campylobacter infecting humans. The US Food and Drug Administration felt that serious questions could be raised about whether use of enrofloxacin posed zero risk to humans. Although the risk to humans may be zero, this is not currently proved with scientific certainty. Campylobacter is an avian gut commensal, and Campylobacter gastroenteritis in humans is sometimes associated with the consumption of undercooked chicken, although handling of raw chicken and preparation and consumption of chicken in the home have also been associated with reduced risks of Campylobacter infections. Campylobacter resistance is up to 20% in parts of the developed world. Enrofloxacin is a fluoroquinolone whose mechanism of action is very similar to ciprofloxacin; it is used in veterinary practice to treat respiratory infections of poultry, when it is added to water or to the feed and may be used to medicate a whole flock. Scientists and lobbyists have often pointed out that there is no evidence of the transfer of antibiotic resistance in food animals to humans, but given that Campylobacter does not naturally occur in humans (unless they eat foods with campylobacter) and that ciprofloxacin resistance has increased among people who travel to countries with widespread abuse of ciprofloxacin, it has been tempting for advocates who oppose consumption of meat and/or use of animal antibiotics to conclude that ciprofloxacin-resistant Campylobacter in humans could arise from eating chicken contamined with enrofloxacin-resistant Campylobacter, despite the lack of scientific evidence. Indeed in countries where fluoroquinolone use is restricted, fluoroquinolone resistance in Campylobacter is uncommon.[1] Sadly, a preoccupation with fear of resistance has led many scientists and regulators to overlook the fact that appropriate use of antibiotics in animal feeds can reduce human exposures to susceptible bacteria. For example, in Australia, where enrofloxacin is not used, ciprofloxacin resistance rates in human isolates are relatively low (comparable to historical rates reported among domestically acquired cases of campylobacteriosis in the United States, but much smaller than rates in Spain, Thailand, and other countries where ciprofloxacin is over-used). However, rates of campylobacteriosis in the population are many time greater than in the United States. It remains to be seen whether the 2005 ban on enrofloxacin in the United States will be

followed by increases in campylobacteriosis rates -- a possibility that FDA declined to consider in arguing for a ban.

The illegal use of amantadine to medicate poultry in the South of China and other parts of southeast Asia, means that although the H5N1 strain that appeared in Hong Kong in 1997 was amantadine sensitive, the more recent strains have all been amantadine resistant. This seriously reduces the treatment options available to doctors in the event of an influenza pandemic.

Eighteen UK organisations banded together in November 1997 to set guidelines on the use of antibiotics in farm animals, in order to address the concerns of the larger public. The consortium is called RUMA (Responsible use of Medicine in Agriculture Alliance) Members of this consortium include the British Poultry Council and various industry and pharmaceutical firms. The European Union has banned the use of all antibiotics as growth promoters since 1 January 2006.

Alternatives to antibiotics

Prevention

Washing hands properly reduces the chance of getting infected or spreading infection. Thoroughly washing or avoiding of raw foods such as fruits, vegetables, raw eggs, and undercooked meat can also reduce the chance of an infection.

Vaccines

Vaccines do not suffer the problem of resistance because a vaccine enhances the body's natural defenses, while an antibiotic operates separately from the body's normal defenses. Nevertheless, new strains may evolve that escape immunity induced by vaccines.

While theoretically promising, anti-staphylococcal vaccines have shown limited efficacy, because of immunological variation between Staphylococcus species, and the limited duration of effectiveness of the antibodies produced. Development and testing of more effective vaccines is under way.

Phage therapy

Phage therapy is a more recent alternative that can cope with the problem of resistance.

Development of newer antibiotics

The resistance problem demands that a renewed effort be made to seek antibacterial agents effective against pathogenic bacteria resistant to current antibiotics. One of the possible strategies towards this objective is the rational localization of bioactive phytochemicals. Plants have an almost limitless ability to synthesize aromatic substances, most of which are phenols or their oxygen-substituted derivatives such as tannins. Most are secondary metabolites, of which at least 12,000 have been isolated, a number estimated to

be less than 10% of the total. In many cases, these substances serve as plant defense mechanisms against predation by microorganisms, insects, and herbivores. Many of the herbs and spices used by humans to season food yield useful medicinal compounds including those having antibacterial activity.

Traditional healers have long used plants to prevent or cure infectious conditions. Many of these plants have been investigated scientifically for antimicrobial activity and a large number of plant products have been shown to inhibit growth of pathogenic bacteria. A number of these agents appear to have structures and modes of action that are distinct from those of the antibiotics in current use, suggesting that cross-resistance with agents already in use may be minimal.

Applications

Antibiotic resistance is an important tool for genetic engineering. By constructing a plasmid which contains an antibiotic resistance gene as well as the gene being engineered or expressed, a researcher can ensure that when bacteria replicate, only the copies which carry along the plasmid survive. This ensures that the gene being manipulated passes along when the bacteria replicates.

The most commonly used antibiotics in genetic engineering are generally "older" antibiotics which have largely fallen out of use in clinical practice. These include:

- ampicillin
    - kanamycin
- tetracycline
    - chloramphenicol

Industrially the use of antibiotic resistance is disfavored since maintaining bacterial cultures would require feeding them large quantities of antibiotics. Instead, the use of auxotrophic bacterial strains (and function-replacement plasmids) is preferred.

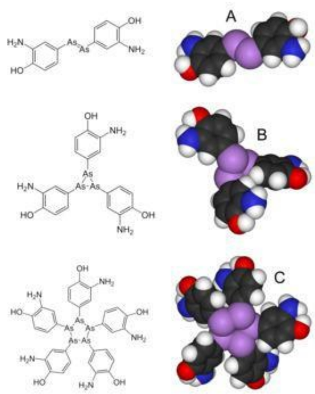
Arsphenamine



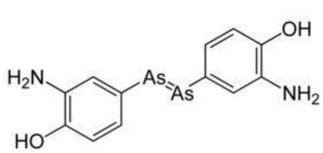
The structure of *arsphenamine* was believed to be *A* until 2005, when new research suggested the true structure was in fact a mixture of the trimer *B* and the pentamer *C*

Arsphenamine is a drug that was used to treat syphilis and trypanosomiasis. It was the first modern chemotherapeutic agent. Sahachiro Hata discovered the anti-syphilitic activity of this compound in 1908 in the laboratory of Paul Ehrlich, during a survey of hundreds of newly-synthesized organic arsenical compounds. Ehrlich had theorized that by screening many compounds a drug could be discovered with anti-microbial activity. Ehrlich's team began their search for such a magic bullet among chemical derivatives of the dangerously-toxic drug atoxyl. This was the first organized team effort to optimize the biological activity of a lead compound through systematic chemical modifications, the basis for nearly all modern pharmaceutical research.

Arsphenamine was marketed under the trade name *Salvarsan* in 1910. It was also called *606*, because it was the 606th compound synthesized for testing. Salvarsan was the first organic anti-syphillitic, and a great improvement over the inorganic mercury compounds that had been used previously. A more soluble (but slightly less effective) arsenical compound, Neosalvarsan, (neoarsphenamine), became available in 1912. These arsenical compounds came with considerable risk of side effects, and they were supplanted as treatments for syphilis in the 1940s by penicillin.

The bacterium that causes syphilis is a spirochete, Treponema pallidum. Arsphenamine is not toxic to spirochetes until it has been converted to an active form by the body, so the discovery of this drug could not have been made without Hata's animal testing. After leaving Erlich's laboratory, Hata continued parallel investigation of the new medicine in Japan.[1]

The structure was believed to be:



However, in 2005, researchers determined Arsphenamine's structure to be a compound of a cyclic trimer and a pentamer.

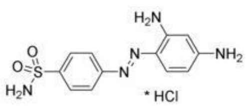
Prontosil



Systematic (IUPAC) name

4-[(2,4-diaminophenyl)azo]benzenesulfonamide

Identifiers

CAS number 103-12-8

Chemical data

Formula C***12***H***13***N***5***O***2***S - HCl

Mol. weight 291.33

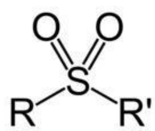
Therapeutic considerations

Routes oral

Prontosil, the first commercially available antibiotic, was developed by a research team at the Bayer Laboratories in Germany. Its discovery and development opened a new era in medicine. The molecule, first synthesized by Bayer chemists Josef Klarer and Fritz Mietzsch, was tested and found effective against some important bacterial infections in mice by Gerhard Domagk, who subsequently received the 1939 Nobel Prize in Medicine. Prontosil was the result of five years of research and testing involving thousands of chemical substances. The definitive tests were done in 1932, but results were not published until 1935, after I.G. Farben had obtained a patent. It was quickly found by a French research team at the Pasteur Institute that Prontosil, a nearly insoluble red azo dye, is broken down in the body, releasing a much simpler, colorless molecule sulfanilimide through a process called

"bioactivation." Sulfanilamide, the active portion of the Prontosil molecule, was out of patent, cheap to produce, easy to link into other molecules, and soon widely available in hundreds of forms. As a result, Prontosil failed to make the profits in the marketplace hoped for by Bayer. Although quickly eclipsed by newer sulfa drugs and, in the mid-1940s and through the 1950s, penicillin and a string of newer antibiotics that proved more effective against more types of bacteria, Prontosil remained on the market until the 1960s. Prontosil's discovery ushered in the era of antibiotics and had a profound impact on pharmaceutical research, drug laws, and medical history.

Sulfone



The structure of the sulfonyl group

A *sulfone* is a chemical compound containing a sulfonyl functional group attached to two carbon atoms. The central sulfur atom is twice double bonded to oxygen and has two further hydrocarbon substituents. The general structural formula is R-S(=O)(=O)-R' where R and R' are the organic groups. The use of the alternative name *sulphone* is discouraged by IUPAC. Sulfides are often the starting materials for sulfones by organic oxidation through the intermediate formation of sulfoxides. For example dimethyl sulfide is oxidized to dimethyl sulfoxide and then to dimethyl sulfone.

In the Ramberg-Bäcklund Reaction and the Julia olefination sulfones are converted to alkenes.

A sulfone can also be any of various organic sulfur compounds having a sulfonyl group attached to two carbon atoms, especially such a compound formerly used as an antibiotic to treat leprosy, dermatitis herpetiformis, tuberculosis, or Pneumocystis Carinii Pneumonia (PCP).

Antifungals

An *antifungal drug* is medication used to treat fungal infections such as athlete's foot, ringworm and candidiasis (thrush), as well as serious systemic infections like cryptococcal meningitis. Such drugs can be either prescription drugs or OTC drugs.

List of antifungal drugs

Antifungals work by exploiting differences between mammalian and fungal cells to kill off the fungal organism without significantly harming the host. Unlike bacteria, both fungi and humans are eukaryotes. The basic structure of fungal cells and human cells is nearly identical. This means it is more difficult to find a target for an antifungal medication to attack

that does not also exist in the infected organism. Consequently, there are often side-effects to these drugs. Some of these side-effects can be life-threatening.

There are several classes of antifungal drugs.

Polyene antibiotic

The polyene antibiotics bind with sterols in the fungal cell wall, principally ergosterol. This causes the cell's contents to leak out and the cell dies. Animal cells contain cholesterol instead of ergosterol and so they are much less susceptible.

- Nystatin
Amphotericin B
Natamycin
Rimocidin
Filipin
Pimaricin

Imidazole and triazole

The imidazole and triazole groups of antifungal drugs inhibit the enzyme cytochrome P450 14±-demethylase. This enzyme converts lanosterol to ergosterol, and is required in fungal cell wall synthesis. These drugs also block steroid synthesis in humans.

Imidazoles:

- Miconazole
Ketoconazole
Clotrimazole
Econazole
Mebendazole
Bifonazole
Butoconazole
Fenticonazole
Isoconazole
Oxiconazole
Sertaconazole
Sulconazole
Thiabendazole
Tioconazole

The triazoles are newer, and are less toxic and more effective:

- Fluconazole
Itraconazole
Ravuconazole
Posaconazole
Voriconazole

Allylamines

Allylamines inhibit the enzyme squalene epoxidase, another enzyme required for ergosterol synthesis:

- Terbinafine - marketed as Lamisil in North America and the UK
Amorolfine
Naftifine
Butenafine

Echinocandin

Echinocandins inhibit the synthesis of glucan in the cell wall, probably via the enzyme 1,3-² glucan synthase:

- Anidulafungin
Caspofungin
Micafungin

Others

Others:

- Flucytosine is an antimetabolite.
Griseofulvin binds to polymerized microtubules and inhibits fungal mitosis.
Fluocinonide
Gentian Violet
Ciclopirox is a fungicidal
Tolnaftate is a fungicidal

Alternatives:

- Tea tree oil -- ISO 4730 ("Oil of Melaleuca, Terpinen-4-ol type")

Dandruff shampoos

Antifungal drugs are often found in dandruff shampoos. Among the most common are pyrithione zinc and selenium sulfide.

Garlic (Allium sativum) is a perennial plant in the family Alliaceae and genus Allium, closely related to the onion, shallot, and leek. It does not grow in the wild, and is thought to have arisen in cultivation, probably descended from the species Allium longicuspis, which grows wild in south-western Asia.[1] Garlic has been used throughout all of recorded history for both culinary and medicinal purposes.

The portion of the plant most often consumed is an underground storage structure called a *head*. A head of garlic is composed of a dozen or more discrete *cloves*, each of which is a botanical bulb, an underground structure comprised of thickened leaf bases. Each garlic clove may often be composed of just one leaf base, unlike onions, which almost always have multiple layers. The above-ground portions of the garlic plant are also sometimes consumed, particularly while immature and tender.

Garlic has a powerful pungent or "hot" flavor when raw, which mellows considerably when it is cooked. Raw or cooked, garlic is noted for its strong characteristic odor. [2]

Biology and chemistry

Because of its wide cultivation, the origins of garlic are not fully certain. It is related to onions and lilies, and cultivated in the same manner as the shallot. The domesticated garlic plant does not produce seeds, but is grown from bulbs. These bulbs are the part of the plant most commonly eaten, though some cooks also use the early spring shoots. These shoots are often pickled in Russia and states of the Caucasus and eaten as an appetizer. A common error made by novice cooks is to misinterpret the word "clove" as meaning the entire garlic head (naturally occurring cluster of cloves, depending on the species) rather than one of its segments, thereby wildly exaggerating the amount of garlic in a recipe.

A garlic head is generally four to eight centimeters in diameter, white to pinkish or purple, and is composed of numerous (8 - 25) discrete bulbs. The foliage comprises a central stem 25 - 100 cm tall, with flat or keeled (but not tubular) leaves 30 - 60 cm long and 2 - 3 cm broad. The flowers are produced in a small cluster at the top of the stem, often together with several bulblets, and surrounded by a papery basal spathe; each flower is white, pink or purple, with six tepals 3 - 5 millimetres long. The flowers are commonly abortive and rarely produce any seeds.

The garlic plant has long, narrow, flat, obscurely keeled leaves. The head (compound bulb) has a flaky, mostly white outer layers of skin like that of an onion. Inside are 8-25 cloves, or smaller bulbs. From these, new bulbs can be procured by planting out in late winter or early spring.

The percentage composition of the bulbs is given by E. Solly (Trans. Hon. Soc. Loud., new ser., iii. p. 60) as water 84.09 %, organic matter 13.38 %, and inorganic matter 1.53 % - that of the leaves being water 87.14 %, organic matter 11.27 % and inorganic matter 1.59 %.

Like other members of the onion family, garlic actually creates the chemicals that give it its sharp flavor when the plant's cells are damaged. When a cell of a garlic clove is broken by chopping, chewing, or crushing, enzymes stored in cell vacuoles trigger the breakdown of several sulfur-containing compounds stored in the cell fluids. The resultant compounds are

responsible for the sharp or hot taste and strong smell of garlic. Some of the compounds are unstable and continue to evolve over time. Among the members of the onion family, garlic has by far the highest concentrations of initial reaction products, making garlic much more potent than onions, shallots, or leeks.[3] Although people have come to enjoy the taste of garlic, these compounds are believed to have evolved as a defensive mechanism, deterring animals like birds, insects, and worms from eating the plant.[4]

A large number of sulfur compounds contribute to the smell and taste of garlic. Diallyl disulfide is believed to be an important odor component. Allicin has been found to be the compound most responsible for the spiciness of raw garlic. This chemical opens thermoTRP (transient receptor potential) channels that are responsible for the burning sense of heat in foods. The process of cooking garlic removes allicin, thus mellowing its spiciness.[5]

Uses

Culinary use

Garlic is most often used as a seasoning or a condiment. When crushed or finely chopped it yields allicin, a powerful antibiotic and anti-fungal compound (phytoncide). It also contains alliin, ajoene, enzymes, vitamin B, minerals, and flavonoids.

Garlic is widely used in many forms of cooking for its strong flavor, which is considered to enhance many other flavors. Depending on the form of cooking and the desired result, the flavor is either mellow or intense. It is often paired with onion, tomato, and/or ginger.

In culinary preparation, it is necessary to remove the parchment-like skin from individual cloves before chopping. Lightly crushing the cloves with the ball of the hand or flat of a knife makes this job much easier. Neither garlic nor herbs should be stored while covered in cooking oil as it is possible for botulism organisms to grow in the oxygen-free oil.

When eaten in quantity, garlic may be strongly evident in the diner's sweat and breath the following day. This is because garlic's strong smelling sulfur compounds are metabolized forming allyl methyl sulfide. Allyl methyl sulfide (AMS) cannot be digested and is passed into the blood. It is carried to the lungs and the skin where it is excreted. Since digestion takes several hours, and release of AMS several hours more, the effect of eating garlic may be present for a long time.

The well-known phenomenon of "garlic breath" is alleged to be alleviated by eating fresh parsley. This is, therefore, included in many garlic recipes, e.g. Pistou and Persillade. However, since garlic breath results mainly from digestive processes placing compounds such as AMS in the blood, and AMS is then released through the lungs over the course of many hours, eating parsley is at best a temporary fix. One way of accelerating the release of AMS from the body is the use of a sauna. Because of its strong odor, garlic is sometimes called the "stinking rose".

Hardneck garlic varieties feature a seedpod that grows atop a leafless stalk known as a "scape". Immature scapes are tender and edible. They are also known as "garlic spears", "stems", or "tops". Scapes generally have a milder taste than cloves. They are often used in stir frying or prepared like asparagus.

Source: Balch p 97[6]

Some scientific research indicates that garlic can have some health benefits, such as preventing and fighting common cold[7],diminishment of platelet aggregation[8]; a meta-analysis showing significant (8% compared to placebo) lowering of Low density lipoprotein carrying cholesterol (LDL-C) [9]; treatment of hyperlipidaemia[10]; the significant inhibition of atherosclerosis via the use of aged garlic extract Kyolic[11]; and the protective nature of chronic garlic intake on elastic properties of aorta in the elderly[12]. Regular and prolonged use of therapeutic amounts of aged garlic extracts lower blood homocysteine levels, and prevent some complications of diabetes mellitus. It may have some cancer-fighting properties because it is high in diallyl sulphide (DADs), believed to be an anticarcinogen.[13]

In modern naturopathy, garlic is used as a treatment for intestinal worms, both orally and as an anal suppository.

Garlic cloves continue to be used by aficionados as a remedy for infections (especially chest problems), digestive disorders, and fungal infections such as thrush. They are claimed to be an effective long-term remedy for cardiovascular problems reducing excessive blood cholesterol levels, atherosclerosis, the risk of thrombosis, and hypertension but these claims are disputed, as there has been no clinical trial that has demonstrated any such benefits. Whole cloves used as vaginal suppositories are sometimes used as a home remedy for Candidiasis (yeast infections). Garlic is also alleged to help regulate blood sugar levels, and

so can be helpful in late-onset diabetes, though people taking insulin should not consume medicinal amounts of garlic without consulting a physician. In such applications, garlic must be fresh and uncooked, or the allicin will be lost.

Dietary supplements in pill form, as are commonly available, claim to possess the medicinal benefits of garlic, without (in the words of one manufacturer) "the unsocial qualities associated with fresh garlic cloves".

History

From the earliest times garlic has been used as an article of diet. It is very widely used in Lebanese cuisine. Many Lebanese salads contain a garlic sauce. It formed part of the food of the Israelites in Egypt (Numb. xi. 5) and of the labourers employed by Khufu in constructing the pyramid. Garlic is still grown in Egypt, but the Syrian variety is the kind most esteemed now (see Rawlinson's Herodotus, 2.125).

It was consumed by the ancient Greek and Roman soldiers, sailors and rural classes (cf. Virg. Ed. ii. II), and, as Pliny tells us (N.H. xix. 32), by the African peasantry. Galen eulogizes it as the "rustic's theriac" (cure-all) (see F Adams's Paulus Aegineta, p. 99), and Alexander Neckam, a writer of the 12th century (see Wright's edition of his works, p. 473, 1863), recommends it as a palliative of the heat of the sun in field labor.

Pliny the Elder, in his Natural History, (N.H. xx. 23) gives an exceedingly long list of scenarios in which it was considered beneficial. Dr. T. Sydenham valued it as an application in confluent smallpox, and, says Cullen (Mat. Med. ii. p. 174, 1789), found some dropsies cured by it alone. Early in the 20th century, it was sometimes used in the treatment of pulmonary tuberculosis or phthisis.

Garlic was rare in traditional English cuisine (though it is said to have been grown in England before 1548), and has been a much more common ingredient in Mediterranean Europe. Garlic was placed by the ancient Greeks on the piles of stones at cross-roads, as a supper for Hecate (Theophrastus, Characters, The Superstitious Man); and according to Pliny, garlic and onions were invoked as deities by the Egyptians at the taking of oaths. The inhabitants of Pelusium in lower Egypt, who worshipped the onion, are said to have had an aversion to both onions and garlic as food.

To prevent the plant from running to leaf, Pliny (Nat. Hist. xix. 34) advised bending the stalk downward and covering with earth; seeding, he observes, may be prevented by twisting the stalk (by "seeding", he most likely means the development of small, less potent bulbs).

Superstition and mythology

Garlic has been seen as a force for both good and evil. A Christian myth says that after Satan left the Garden of Eden, garlic arose in his left footprint, and onion in the right.[14] Even in Europe, though, many cultures have turned to garlic as a protective force or white magic, perhaps because of its reputation as a powerful preventative medicine.[15] Central European folk beliefs considered garlic a powerful ward against devils, werewolves, and

vampires.[15] To ward off vampires, garlic could be worn on one's person, hung in windows, or rubbed on chimneys and keyholes.[16]

Classification

Classification of culinary garlic can be complex, with numerous cultivars being grown. The broadest division is into "hardneck" and "softneck" types; very broadly speaking, hardnecks have more intense flavours (which are more closely related to their wild ancestor) but lesser storage capabilities, while conversely softnecks are excellent "keepers" but often milder (those are broad-brush simplifications with numerous exceptions and half-exceptions). Within those two types, there are usually felt to be three subdivisions of hardnecks and two of softnecks.

The "wild garlic", "crow garlic" and "field garlic" of Britain are the species Allium ursinum, A. vineale and A. oleraceum, respectively. In North America, "wild garlic" or "crow garlic" is Allium vineale, and along with "wild onion" (also known as "meadow garlic" or "wild garlic") Allium canadensis, are common weeds in fields. Elephant garlic is a variant of the leek species, A. ampeloprasum, and is larger and milder than true garlic.[17]

Preservation

The types differ not only in culinary qualities, but in storage potential. Under good storage conditions, which are not hard to achieve (room temperature and medium to low humidity), one can hope for these results:

- Asiatic, Turban and Porcelain types: a few months
- Rocambole and Purple Stripe types: 6 to 8 months
- Artichoke types: 8 to 10 months
- Silverskin (including Creole) types: up to a full year

Rocamboles, however, have a tendency to dehydrate in storage under dry conditions (less than about 50% humidity).

The bulbs are best preserved hung in a dry place. If of fair size, four to six of them weigh about 500 g (1 lb). Also, it is very important to keep them out of the sun. A dark corner of the room is best.

Do not store garlic in oil at room temperature. See *Caution*, below.

Caution

- Cases of botulism have been caused by consuming garlic-in-oil preparations. It is important to add acid when creating these mixtures and to keep them refrigerated to retard bacterial growth. [18]
- While culinary quantities are generally safe, during pregnancy and lactation garlic can cause digestive problems such as heartburn, and babies may dislike the taste in breast milk.
- The medicinal effects of taking garlic long-term are largely unknown, and no FDA approved study has been performed.

Trivia

- South Korea is the largest consumer of garlic.
- In the United States, Gilroy, California promotes itself as "Garlic Capital of the World", and hosts the Gilroy Garlic Festival every summer.
- In 2005, a poll of 2,000 people revealed garlic to be Britain's 6th favourite culinary vegetable. [1]
- In the televised cartoon shorts, before he used spinach as a source of superhuman strength, comic book character Popeye's ancestor Hercules would sniff fresh bulbs of unpeeled garlic.
- Garlic is Wario's favorite food. When he eats it in WarioWare: Touched!, he becomes Wario-Man.

Antiparasitic agents

Antiparasitics are a class of medications which are indicated for the treatment of infection by parasites such as nematodess, cestodes, trematodes, infectious protozoa, and amoebas.

Antinematodes

- Mebendazole (for most nematode infections)

Pyrantel pamoate (for most nematode infections)
Thiabendazole (for roundworm infections)
Diethycarbazine (for treatment of Lymphatic filariasis)

Anticestodes

- Niclosamide (for tapeworm infections)

Parziquantel (for tapeworm infections)

Antitrematodes

- Parziquantel

Antiamoebics

- Rifampin
Amphotericin B

Antiprotozoals

- Melarsoprol (for treatment of sleeping sickness caused by Trypanosoma brucei)

Anthelmintics

Anthelmintics (in the U.S., *antihelminthics*) are drugs that expel parasitic worms (helminths) from the body, by either killing or stunning them. A traditional remedy of this type is often called a *vermifuge*.

Examples of drugs used as anthelmintics include:

- Albendazole - Effective against: threadworms, roundworms, whipworms, tapeworms, hookworms
Diethylcarbamazine - Effective against: Wuchereria bancrofti, Brugia malayi, Brugia timori, tropical pulmonary eosinophilia, loiasis
Mebendazole - Effective against: pinworms, roundworms and hookworms
Niclosamide - Effective against: tapeworms
Ivermectin - Effective against: most common intestinal worms (except tapeworms)
Suramin
Thiabendazole - Effective against: roundworms, hookworms

According to the United States Army Field Manual, there are several other common products which can be used (albeit dangerously) as antihelmintics:

- Saltwater. Mix 4 tablespoons of salt (NaCl) in 1 quart of water and drink. Never repeat this treatment.
- Tobacco - Eat 1 to 1.5 cigarettes. The nicotine in the tobacco will kill or stun the worms long enough for you to expel them.
- Kerosene - At the most, drink 2 tablespoons of kerosene. If necessary, you can repeat this in several days (1 to 2 days at the least).
- Hot peppers - Peppers are effective only when they are a steady part of your diet. You can eat them raw or add them to food.

Many members of the piperazine family are successful anthelmintics.

Natural anthelmintics include black walnut, wormwood (Artemisia absynthium), clove (Syzygium aromaticum), tansy tea (Tanacetum vulgare), Hagenia (Hagenia abyssinica), and the male fern (Dryopteris filix-mas).

The macroinvertebrate parasites treated in this way include, for instance, tapeworms and roundworms, which infest the intestines.

Antiprotozoal agent

Antiprotozoal agents (ATC code: ATC P01) is a class of pharmaceuticals used in treatment of protozoal infections.

Examples:

- Eflornithine

Furazolidone
Melarsoprol
Metronidazole
Ornidazole
Paromomycin sulfate
Pentamidine
Pyrimethamine
Tinidazole

Antimalarial agents

Antimalarial drugs are designed to prevent or treat malaria. There are many of these drugs currently on the market. Here is a partial list.

Antimalarial drugs currently used for treatment

- mefloquine (Lariam ®)

chloroquine
fansidar (pyrimethamine, sulfadoxine)
amodiaquine

- quinine/quinidine
- artemisinin/artemether/artesunate

atovaquone
lumefatrine

Antimalarial drugs currently used for prophylaxis

- mefloquine
  chloroquine
  proguanil
  pyrimethamine (daraprim)
- doxycycline
  - hydroxychloroquine (Plaquenil)

Antiseptics

Antiseptics (Greek ±½Ä¹, against, and Ã·ÀÄ¹º¿Â, putrefactive) are antimicrobial substances that are applied to living tissue/skin to to reduce the possibility of infection, sepsis, or putrefaction. They should generally be distinguished from antibiotics that destroy microorganisms within the body, and from disinfectants, which destroy microorganisms found on non-living objects. Some antiseptics are true germicides, capable of destroying microbes (bacteriocidal), whilst others are bacteriostatic and only prevent or inhibit their growth. Antibacterials are antiseptics that only act against bacteria.

Use in surgery

The widespread introduction of antiseptic surgical methods followed the publishing of the paper Antiseptic Principle of the Practice of Surgery in 1867 by Joseph Lister, inspired by Louis Pasteur's germ theory of putrefaction. In this paper he advocated the use of carbolic acid (phenol) as a method of ensuring that any germs present were killed. Some of this work was preceded slightly by that of Dr. George H Tichenor and Ignaz Semmelweis.

But every antiseptic, however good, is more or less toxic and irritating to a wounded surface. Hence it is that the antiseptic method has been replaced in the surgery of today by the aseptic method, which relies on keeping free from the invasion of bacteria rather than destroying them when present.

How it works

For the growth of bacteria there must be a certain food supply, moisture, in most cases oxygen, and a certain minimum temperature (see bacteriology). These conditions have been specially studied and applied in connection with the preserving of food and in the ancient practice of embalming the dead, which is the earliest illustration of the systematic use of antiseptics.

In early inquiries a great point was made of the prevention of putrefaction, and work was done in the way of finding how much of an agent must be added to a given solution, in order that the bacteria accidentally present might not develop. But for various reasons this was an inexact method, and to-day an antiseptic is judged by its effects on pure cultures of definite pathogenic microbes, and on their vegetative and spore forms. Their standardization has

been effected in many instances, and a water solution of phenol of a certain fixed strength is now taken as the standard with which other antiseptics are compared.

Some common antiseptics

Alcohols Most commonly used are ethanol (60-90%), 1-propanol (60-70%) and 2-propanol/isopropanol (70-80%) or mixtures of these alcohols. They are commonly reffered to as "surgical alcohol". Used to disinfect the skin before injections are given, often along with iodine (tincture of iodine) or some cationic surfactants (benzalkonium chloride 0.05 - 0.5%, chlorhexidine 0.2 - 4.0% or octenidine dihydrochloride 0.1 - 2.0%).

Quaternary ammonium compounds Also known as Quats or QAC's, include the chemicals benzalkonium chloride (BAC), cetyl trimethylammonium bromide (CTMB), cetylpyridinium chloride (Cetrim), cetylpyridinium chloride (CPC) and benzethonium chloride (BZT). Benzalkonium chloride is used in some pre-operative skin disinfectants (conc. 0.05 - 0.5%) and antiseptic towels. The antimicrobial activity of Quats is inactivated by anionic surfactants, such as soaps. Related disinfectants include chlorhexidine and octenidine.

Boric acid Used in suppositories to treat yeast infections of the vagina, in eyewashes, and as an antiviral to shorten the duration of cold sore attacks. Put into creams for burns. Also common in trace amounts in eye contact solution. Though it is popularly known as an antiseptic, it is in reality only a soothing fluid, and bacteria will flourish comfortably in contact with it.

Chlorhexidine Gluconate A biguanidine derivative, used in concentrations of 0.5 - 4.0% alone or in lower concentrations in combination with other compounds, such as alcohols. Used as a skin antiseptic and to treat inflammation of the gums (gingivitis). The microbicidal action is somewhat slow, but remanent. It is a cationic surfactant, similar to Quats.

Hydrogen peroxide Used as a 6% (20Vols) solution to clean and deodorise wounds and ulcers. More common 1% or 2% solutions of hydrogen peroxide have been used in household first aid for scrapes, etc. However, even this less potent form is no longer recommended for typical wound care as the strong oxidization causes scar formation and increases healing time. Gentle washing with mild soap and water or rinsing a scrape with sterile saline is a better practice.

Iodine Usually used in an alcoholic solution (called tincture of iodine) or as Lugol's iodine solution as a pre- and post-operative antiseptic. No longer recommended to disinfect minor wounds because it induces scar tissue formation and increases healing time. Gentle washing with mild soap and water or rinsing a scrape with sterile saline is a better practice. Novel iodine antiseptics containing iodopovidone/PVP-I (an iodophor, complex of povidone, a water-soluble polymer, with triiodide anions I3-, containing about 10% of active iodine, with the commercial name Betadine) are far better tolerated, don't affect wound healing negativelly and leave a depot of active iodine, creating the so-called "remanent," or persistent, effect. The great advantage of iodine antiseptics is the widest scope of antimicrobial activity, killing all principial pathogenes and given enough time even spores, which are considered to be the most difficult form of microorganisms to be inactivated by disinfectants and antiseptics.

Mercurochrome Not recognized as safe and effective by the U.S. Food and Drug Administration (FDA) due to concerns about its mercury content. Another obsolete organomercury antiseptics include bis-(fenylmercury) monohydrogenborate (Famosept).

Octenidine dihydrochloride A cationic surfactant and bis-(dihydropyridinyl)-decane derivative, used in concentrations of 0.1 - 2.0%. It is similar in its action to the Quats, but is of somewhat broader spectrum of activity. Octenidine is currently increasingly used in continental Europe as a QAC's and chlorhexidine (with respect to its slow action and concerns about the carcinogenic impurity 4-chloroaniline) substitute in water- or alcohol-based skin, mucosa and wound antiseptic. In aqueous formulations, it is often potentiated with addition of 2-phenoxyethanol.

Phenol (carbolic acid) compounds Phenol is germicidal in strong solution, inhibitory in weaker ones. Used as a "scrub" for pre-operative hand cleansing. Used in the form of a powder as an antiseptic baby powder, where it is dusted onto the belly button as it heals. Also used in mouthwashes and throat lozenges, where it has a methadone-like painkilling effect as well as an antiseptic one. Example: TCP. Other phenolic antiseptics include historically important, but today rarely used (sometimes in dental surgery) thymol, today obsolete hexachlorophene, still used triclosan and sodium 3,5-dibromo-4-hydroxybenzenesulfonate (Dibromol).

Sodium chloride Used as a general cleanser. Also used as an antiseptic mouthwash. Only a weak antiseptic effect, due to hyperosmolality of the solution above 0.9%.

Sodium hypochlorite Used in the past, diluted, neutralised and combined with potassium permanganate in the Daquin's solution. Nowadays used only as disinfectant.

Iodine

Name, Symbol, Number: iodine, I, 53

Chemical series halogens

Group, Period, Block: 17, 5, p

Appearance violet-dark gray, lustrous

Atomic mass 126.90447(3) g/mol

Electron configuration [Kr] 4d10 5s2 5p5

Electrons per shell 2, 8, 18, 18, 7

Physical properties

phase solid

Density (near r.t.) 4.933 g·cm3

Melting point 386.85 K (113.7 °C, 236.66 °F)

Boiling point 457.4 K (184.3 °C, 363.7 °F)

Critical point 819 K, 11.7 MPa

Heat of fusion (I*2*) 15.52 kJ·mol1

Heat of vaporization (I*2*) 41.57 kJ·mol1

Heat capacity (25 °C) (I*2*) 54.44 J·mol1·K1

Vapor pressure (rhombic)

P/Pa	1	10	100	1 k	10 k	100 k
at T/K	260	282	309	342	381	457

Atomic properties

Crystal structure orthorhombic

Oxidation states ±1, 5, 7 (strongly acidic oxide)

Electronegativity 2.66 (Pauling scale)

Ionization energies 1st: 1008.4 kJ/mol, 2nd: 1845.9 kJ/mol, 3rd: 3180 kJ/mol

Atomic radius 140 pm

Atomic radius (calc.) 115 pm

Covalent radius 133 pm

Van der Waals radius 198 pm

Miscellaneous

Magnetic ordering nonmagnetic

Electrical resistivity (0 °C) 1.3×107 ©·m

Thermal conductivity (300 K) 0.449 W·m1·K1

Bulk modulus 7.7 GPa

CAS registry number 7553-56-2

Selected isotopes

Main article: Isotopes of iodine

iso	NA	half-life	DM	DE (MeV)	DP
^{127}I	100%	I is stable with 74 neutrons			
^{129}I	syn	1.57×10^{7} y	$Beta^{-}$	0.194	^{129}Xe
^{131}I	syn	8.02070 d	$Beta^{-}$	0.971	^{131}Xe

References

Iodine (IPA: /ÈŒjY(Š)ÌdiÐn/, Greek: iodes, meaning "violet"), is a chemical element in the periodic table that has the symbol I and atomic number 53. Chemically, iodine is the least reactive of the halogens, and the most electropositive halogen after astatine. Iodine is primarily used in medicine, photography and dyes. It is required in trace amounts by most living organisms.

As with all other halogens (members of Group VII in the Periodic Table), iodine forms diatomic molecules, and hence, has the molecular formula of $I2$.

Occurrence on earth

Iodine naturally occurs in the environment chiefly as dissolved iodide in seawater, although it is also found in some minerals and soils. The element may be prepared in an ultrapure form through the reaction of potassium iodide with copper(II) sulfate. There are also several other methods of isolating this element. Although the element is actually quite rare, kelp and certain other plants have the ability to concentrate iodine, which helps introduce the element into the food chain as well as keeping its cost down.

Uses

Iodine is used in pharmaceuticals, antiseptics, medicine, food supplements, dyes, catalysts and photography.

Isotopes

There are 37 isotopes of iodine and only one, 127I, is stable.

In many ways, 129I is similar to 36Cl. It is a soluble halogen, fairly non-reactive, exists mainly as a non-sorbing anion, and is produced by cosmogenic, thermonuclear, and in-situ reactions. In hydrologic studies, 129I concentrations are usually reported as the ratio of 129I to total I (which is virtually all 127I). As is the case with 36Cl/Cl, 129I/I ratios in nature are quite small, 1014 to 1010 (peak thermonuclear 129I/I during the 1960s and 1970s reached about 107). 129I differs from 36Cl in that its half-life is longer (15.7 vs. 0.301 million years), it is highly biophilic, and occurs in multiple ionic forms (commonly, I and IO3) which have different chemical behaviors. This makes it fairly easy for 129I to enter the biosphere as it becomes incorporated into vegetation, soil, milk, animal tissue, etc.

Excesses of stable 129Xe in meteorites have been shown to result from decay of "primordial" 129I produced newly by the supernovas which created the dust and gas from which the solar system formed. 129I was the first extinct radionuclide to be identified as present in the early solar system. Its decay is the basis of the I-Xe radiometric dating scheme, which covers the first 50 million years of solar system evolution.

Effects of various radioiodine isotopes in biology are discussed below.

Notable characteristics

Iodine is a dark-gray/purple-black solid that sublimes at standard temperatures into a purple-pink gas that has an irritating odor. This halogen forms compounds with many elements, but is less active than the other members of its Group VII (halogens) and has some metallic-like properties. Iodine dissolves easily in chloroform, carbon tetrachloride, or carbon disulphide to form purple solutions (It is only slightly soluble in water, giving a yellow solution). The deep blue color of starch-iodine complexes is produced only by the free element.

Many students who have seen the classroom demonstration where iodine crystals are gently heated in a test tube come away with the impression that liquid iodine cannot exist at atmospheric pressure. This misconception arises because sublimation occurs without the intermediacy of liquid. The truth is that if iodine crystals are heated carefully to their melting point of 113.7 °C, the crystals will fuse into a liquid, which will be present under a dense blanket of the vapour.

Descriptive Chemistry

Elemental iodine is poorly soluble in water, with one gram dissolving in 3450 ml at 20 °C and 1280 ml at 50 °C. By contrast with chlorine, the formation of the hypohalite ion (IO–) in neutral aqueous solutions of iodine is negligible.

I*2*+ H*2*0 Ë H+ + I– + HIO (K = 2.0×10-13) [1]

Solubility in water is greatly improved if the solution contains dissolved iodides such as hydroiodic acid, potassium iodide, or sodium iodide. Dissolved bromides also improve water solubility of iodine. Iodine is soluble in a number of organic solvents, including ethanol (20.5 g/100 ml at 15 °C, 21.43 g/100 ml at 25 °C), diethyl ether (20.6 g/100 ml at 17 °C, 25.20

g/100 ml at 25 °C), chloroform, acetic acid, glycerol, benzene (14.09 g/100 ml at 25 °C), carbon tetrachloride (2.603 g/100 ml at 35 °C), and carbon disulfide (16.47 g/100 ml at 25 °C)[2]. Aqueous and ethanol solutions are brown. Solutions in chloroform, carbon tetrachloride, and carbon disulfide are violet.

Elemental iodine can be prepared by oxidizing iodides with chlorine:

$2I^- + Cl_2 \rightarrow I_2 + 2Cl^-$

or with manganese dioxide in acid solution:[1]

$2I^- + 4H^+ + MnO_2 \rightarrow I_2 + 2H_2O + Mn^{++}$

Iodine is reduced to hydroiodic acid by hydrogen sulfide:[3]

$I_2 + H_2S \rightarrow 2HI + S\downarrow$

or by hydrazine:

$2I_2 + N_2H_4 \rightarrow 4HI + N_2$

Iodine is oxidized to iodate by nitric acid:[4]

$I_2 + 10HNO_3 \rightarrow 2HIO_3 + 10NO_2 + 4H_2O$

or by chlorates:[4]

$I_2 + 2ClO_3^- \rightarrow 2IO_3^- + Cl_2$

Iodine is converted in a two stage reaction to iodide and iodate in solutions of alkali hydroxides (such as sodium hydroxide):[1]

$I_2 + 2OH^- \rightarrow I^- + IO^- + H_2O$ K = 30)

$3IO^- \rightarrow 2I^- + IO_3^-$ (K = 10^{20})

History

Iodine was discovered by Bernard Courtois in 1811. He was born to a manufacturer of saltpeter (potassium nitrate, a vital part of gunpowder). At the time France was at war, saltpeter, a component of gunpowder, was in great demand. Saltpeter produced from French niter beds required sodium carbonate, which could be isolated from seaweed washed up on the coasts of Normandy and Brittany. To isolate the sodium carbonate, seaweed was burned and the ash then washed with water. The remaining waste was destroyed by adding sulfuric acid. One day Courtois added too much sulfuric acid and a cloud of purple vapor rose. Courtois noted that the vapor crystallized on cold surfaces making dark crystals. Courtois suspected that this was a new element but lacked the money to pursue his observations.

However he gave samples to his friends, Charles Bernard Desormes (1777 - 1862) and Nicolas Clément (1779 - 1841) to continue research. He also gave some of the substance to Joseph Louis Gay-Lussac (1778 - 1850), a well-known chemist at that time, and to André-Marie Ampère (1775 - 1836). On 29 November 1813 Dersormes and Clément made public Courtois' discovery. They described the substance to a meeting of the Imperial Institute of France. On December 6 Gay-Lussac announced that the new substance was either an element or a compound of oxygen. Ampère had given some of his sample to Humphry Davy (1778 - 1829). Davy did some experiments on the substance and noted its similarity to chlorine. Davy sent a letter dated December 10 to the Royal Society of London stating that he had identified a new element. A large argument erupted between Davy and Gay-Lussac over who identified iodine first but both scientists acknowledged Barnard Courtois as the first to isolate the chemical element.

Notable inorganic iodine compounds

- Ammonium iodide (NH4I)

Caesium iodide (CsI)
Copper(I) iodide (CuI)
Hydroiodic acid (HI)
Iodic acid (HIO3)
Iodine cyanide (ICN)
Iodine heptafluoride (IF7)
Iodine pentafluoride (IF5)
Lead(II) iodide (PbI2)
Lithium iodide (LiI)
Nitrogen triiodide (NI3)
Potassium iodide (KI)

- Sodium iodide (NaI)

Stable iodine in biology

One of the halogens, iodine is an essential trace element; the thyroid hormones, thyroxine and triiodothyronine contain iodine.

Iodine has a single known role in biology: it is an essential trace element since the thyroid hormones, thyroxine (T4) and triiodothyronine (T3) contain iodine. These are made from addition condensation products of the amino acid tyrosine, and are stored prior to release in a protein-like molecule called thryroglobulin. T4 and T3 contain four and three atoms of iodine per molecule, respectively. The thyroid gland actively absorbs iodide ion from the blood to make and release these hormones into the blood, actions which are regulated by a second hormone TSH from the pituitary. Thyroid hormones are phylogenetically very old molecules which are sythesized by most multicellular organisms, and which even have some effect on unicellular organisms.

Thyroid hormones play a very basic role in biology, acting on gene transcription to regulate the basal metabolic rate. The total deficiency of thyroid hormones can reduce basal metabolic rate up to 50%, while in excessive production of thyroid hormones the basal

metabolic rate can be increased by 100%. T4 acts largely as a precursor to T3, which is (with some minor exceptions) the biologically active hormone.

Dietary intake

The United States Food and Drug Administration recommends (21 CFR 101.9 (c)(8)(iv)) 150 micrograms of iodine per day for both men and women. This is necessary for proper production of thyroid hormone. Natural sources of iodine include seaweed, such as kelp and seafood. [1] Salt for human consumption is often enriched with iodine and is referred to as iodized salt.

Iodine deficiency

In areas where there is little iodine in the diet—typically remote inland areas and semi-arid equatorial climates where no marine foods are eaten—iodine deficiency gives rise to goiter, so called endemic goiter. The mechanism is that low amounts of thyroid hormone in the blood due to lack of iodine to make them, give rise to high levels of the pituitary hormone TSH, which in turn stimulates abnormal growth of the thyroid gland. In some such areas, this is now combatted by the addition of small amounts of iodine to table salt in form of sodium iodide, potassium iodide, potassium iodate—this product is known as iodized salt. Iodine compounds have also been added to other foodstuffs, such as flour, in areas of deficiency.

Iodine deficiency is the leading cause of preventable mental retardation, an effect which happens primarily when babies and small children are made hypothyroid by lack of the element (this condition in adults results in mental slowing, but by itself, almost never causes severe or irreversible mental problems). Iodine deficiency remains a serious public health problem in developing countries.

Toxicity of Iodine

Excess iodine has symptoms similar to those of iodine deficiency. Commonly encountered symptoms are abnormal growth of the thyroid gland and disorders in functioning and growth of the organism as a whole.

Elemental iodine, I_2, is deadly poison if taken in larger amounts; if 2-3 grams of it is consumed, it is fatal to humans.

Iodides are similar in toxicity to bromides.

Radioiodine and biology

Radioiodine and the thyroid

The artificial radioisotope 131I (a beta emitter), also known as radioiodine which has a half-life of 8.0207 days, has been used in treating cancer and other pathologies of the thyroid glands. 123I is the radioisotope most often used in nuclear imaging of the kidney and thyroid as well as thyroid uptake scans (used for the evaluation of Grave's disease). The most

common compounds of iodine are the iodides of sodium and potassium (KI) and the iodates (KIO_3).

129I (half-life 15.7 million years) is a product of 130Xe spallation in the atmosphere and uranium and plutonium fission, both in subsurface rocks and nuclear reactors. Nuclear processes, in particular nuclear fuel reprocessing and atmospheric nuclear weapons tests have now swamped the natural signal for this isotope. 129I was used in rainwater studies following the Chernobyl accident. It also has been used as a ground-water tracer and as an indicator of nuclear waste dispersion into the natural environment.

If humans are exposed to radioactive iodine, the thyroid gland will absorb it as if it were non-radioactive iodine, leading to elevated chances of thyroid cancer. Isotopes with shorter half-lifes such as **131**I present a greater risk than those with longer half-lives since they generate more radiation per unit of time. Taking large amounts of regular iodine will saturate the thyroid and prevent uptake. Iodine pills are sometimes distributed to persons living close to nuclear establishments, for use in case of accidents that could lead to releases of radioactive iodine.

- Iodine-123 and iodine-125 are used in medicine as tracers for imaging and evaluating the function of the thyroid.
- Iodine-131 is used in medicine for treatment of thyroid cancer and Grave's disease.
- Uncombined (elemental) iodine is mildly toxic to all living things.
- Potassium iodide (KI tablets, or "SSKI" = "Super-Saturated KI" liquid drops) can be given to people in a nuclear disaster area when fission has taken place, to flush out the radioactive iodine-131 fission product. The half-life of iodine-131 is only eight days, so the treatment would need to continue only a couple of weeks. In cases of leakage of certain nuclear materials without fission, or certain types of dirty bomb made with other than radioiodine, this precaution would be of no avail.

Radioiodine and the kidney

In the 1970s imaging techniques were developed in California to utilize radioiodine in diagnostics for renal hypertension.

Non-hormone-related applications of iodine

- Tincture of iodine (3% elemental iodine in water/ethanol base) is an essential component of any emergency survival kit, used both to disinfect wounds and to sanitize surface water for drinking (3 drops per liter, let stand for 30 minutes). Alcohol-free iodine solutions such as Lugol's iodine, as well as other free iodine-providing antiseptics iodophors, are also available as effective elemental iodine sources for this purpose.
- Iodine compounds are important in the field of organic chemistry and are very useful in medicine.
- Silver iodide is used in photography.

- Tungsten iodide is used to stabilize the filaments in light bulbs.
- Nitrogen triiodide is an explosive, too unstable to be used commercially, but is commonly used in college pranks.

Precautions for stable iodine

Direct contact with skin can cause lesions, so it should be handled with care. Iodine vapor is very irritating to the eye and to mucous membranes. Concentration of iodine in the air should not exceed 1 mg/m^3 (eight-hour time-weighted average). When mixed with ammonia, it can form nitrogen triiodide which is extremely sensitive and can explode unexpectedly.

Clandestine Use

In the United States, the Drug Enforcement Agency (DEA) regards iodine and compounds containing iodine (ionic iodides, iodoform, ethyl iodide, and so on) as reagents useful for the clandestine manufacture of methamphetamine. Persons who attempt to purchase significant quantities of such chemicals without establishing a legitimate use are likely to find themselves the target of a DEA investigation. Persons selling such compounds without doing due diligence to establish that the materials are not being diverted to clandestine use may be subject to stiff fines [5][6]

Alcohol

In chemistry, an *alcohol* is any organic compound in which a hydroxyl group (-OH) is bound to a carbon atom of an alkyl or substituted alkyl group. The general formula for a simple acyclic alcohol is $C_nH_{2n+1}OH$.

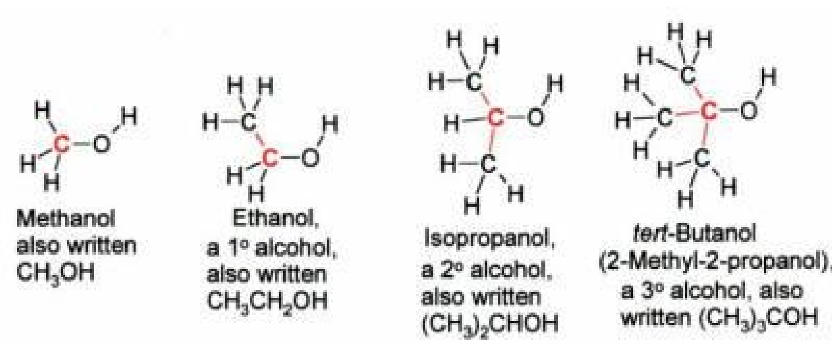
In general usage, *alcohol* refers almost always to ethanol, also known as *grain alcohol*, a strongly-smelling, colorless, volatile liquid formed by the fermentation of sugars. It also often refers to any beverage that contains ethanol (see alcoholic beverage). This sense underlies the term alcoholism (addiction to alcohol). Other forms of alcohol are usually described with a clarifying adjective, as in isopropyl alcohol or by the suffix -ol, as in isopropanol.

Structure

The functional group of an alcohol is a hydroxyl group bonded to an sp^3 hybridized carbon. It can therefore be regarded as a derivative of water, with an alkyl group replacing one of the hydrogens. If an aryl group is present rather than an alkyl, the compound is generally called a phenol rather than an alcohol. Also, if the hydroxyl group is bonded to one of the sp^2 hybridized carbons of an alkenyl group, the compound is referred to as an enol. The oxygen in an alcohol has a bond angle of around 109° (c.f. 104.5° in water), and two nonbonded electron pairs. The O-H bond in methanol (CH3OH) is around 96 picometres long.

Primary, secondary, and tertiary alcohols

There are three major subsets of alcohols- 'primary' (1°), 'secondary' (2°) and 'tertiary' (3°), based upon the number of carbons the C-OH carbon (shown in red) is bonded to. Methanol is the simplest 'primary' alcohol. The simplest secondary alcohol is isopropanol (propan-2-ol), and a simple tertiary alcohol is tert-butanol (2-methylpropan-2-ol).



The phenols with parent compound phenol have a hydroxyl group (attached to a benzene ring) just like alcohols but differ sufficiently in properties to warrant a separate treatment.

Methanol and ethanol

The simplest and most commonly used alcohols are methanol (common name methyl alcohol) and ethanol (ethyl alcohol), with the structures shown above. Methanol was formerly obtained by the distillation of wood and called "wood alcohol." It is now a cheap commodity, the chemical product of carbon monoxide reacting with hydrogen under high pressure. In common usage, "alcohol" often refers to ethanol or "grain alcohol." Methylated spirits ("Meths"), also called "surgical spirits," is a form of ethanol rendered undrinkable by

the addition of methanol. Aside from its primary use in alcoholic beverages, ethanol is also used as a highly controlled industrial solvent and raw material.

Automotive

Alcohol is often used as a automotive fuel. Ethanol and methanol can be made to burn more cleanly than gasoline or diesel. Alcohol was once commonly used as an antifreeze in automobile radiators. And to add to an internal combustion engines performance Methanol may be injected into turbocharged and supercharged engines to cool the air intake charge. Doing this provides a denser air charge.

Scientific, medical, and industrial

Alcohols are in wide use in industry and science as reagents solvents. Because of its low toxicity and ability to dissolve non-polar substances, ethanol is often used as a solvent in medical drugs, perfumes, and vegetable essences such as vanilla. In organic synthesis, alcohols frequently serve as versatile intermediates.

Ethanol is often used as an antiseptic, to disinfect the skin before injections are given, often along with iodine. Ethanol-based soaps are now becoming commonplace within restaurants and are particularly convenient as they do not require drying due to the volatility of the molecule.

Cuisine

In the kitchen, alcoholic beverages are added to dishes not only for their inherent flavors, but also because the alcohol dissolves flavor compounds that water cannot.

Ethanol is commonly used in beverages to promote flavor, reduce social inhibitions, or induce a euphoric intoxication commonly known as drunkenness.

Effects of alcohol on the body

Ethanol is a drug, with potential for overdose or toxic poisoning if taken in excessive quantities. Alcoholism, the physiological or psychological dependency on ethanol, is one of the most common drug addictions (caffeine causes chemical dependency, but not the mental longing known as addiction) in the world. Upon cessation or decrease of use, the physiological dependency can lead to physical withdrawal symptoms, such as restlessness, trouble sleeping, "the shakes," or even death. Not everyone who abuses alcohol becomes physiologically dependent upon it, but can become psychologically addicted to it, similar to marijuana. Psychological addiction produces no physical withdrawal symptoms upon cessation of drinking alcohol, but the urge, or craving, to drink again can become quite intense and irresistible.

Alcohol and politics

Ethanol for consumption has been regulated by taxation. Those who manufacture it for other purposes often avoid this expense by "denaturing" it in a manner that renders it unfit for drinking. A common way to do this is by the addition of denatonium benzoate or methanol. "SD-40" and "SD Alcohol" sometimes followed by "40-B" are designations that were established by the United States' Bureau of Alcohol, Tobacco, Firearms and Explosives for this formulation.

Sources

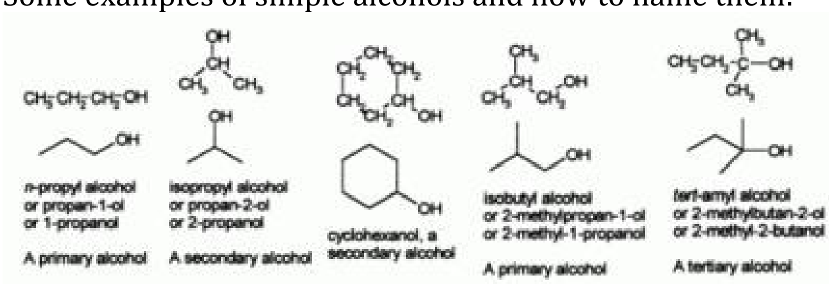
Many alcohols can be created by fermentation of fruits or grains with yeast, but only ethanol is commercially produced this way — chiefly for fuel and drink. Other alcohols are generally produced by synthetic routes from natural gas, petroleum, or coal feed stocks; for example, via acid catalyzed hydration of alkenes.

Nomenclature

Systematic names

In the IUPAC system, the name of the alkane chain loses the terminal "e" and adds "ol", e.g. "methanol" and "ethanol". When necessary, the position of the hydroxyl group is indicated by a number between the alkane name and the "ol": propan-1-ol for CH3CH2CH2OH, propan-2-ol for CH3CH(OH)CH3. Sometimes, the position number is written before the IUPAC name: 1-propanol and 2-propanol. If a higher priority group is present (such as an aldehyde, ketone or carboxylic acid), then it is necessary to use the prefix "hydroxy", for example: 1-hydroxy-2-propanone (CH_3COCH_2OH).

Some examples of simple alcohols and how to name them:



Common names for alcohols usually take the name of the corresponding alkyl group and add the word "alcohol", e.g. methyl alcohol, ethyl alcohol or tert-butyl alcohol. Propyl alcohol may be n-propyl alcohol or isopropyl alcohol depending on whether the hydroxyl group is bonded to the 1st or 2nd carbon on the propane chain. Isopropyl alcohol is also occasionally called sec-propyl alcohol.

As mentioned above alcohols are classified as primary (1°), secondary (2°) or tertiary (3°), and common names often indicate this in the alkyl group prefix. For example $(CH_3)_3COH$ is a tertiary alcohol is commonly known as tert-butyl alcohol. This would be named 2-methylpropan-2-ol under IUPAC rules, indicating a propane chain with methyl and hydroxyl groups both attached to the middle (#2) carbon.

An alcohol with two hydroxyl groups is commonly called a "glycol", e.g. HO-CH**2**-CH**2**-OH is ethylene glycol. The IUPAC name is ethane-1,2-diol, "diol" indicating two hydroxyl groups, and 1,2 indicating their bonding positions. Geminal glycols (with the two hydroxyls on the same carbon atom), such as ethane-1,1-diol, are generally unstable. For three or four groups, "triol" and "tetraol" are used.

Etymology

The word "alcohol" almost certainly comes from the Arabic language (the "al-" prefix being the Arabic definite article); however, the precise origin is unclear. It is likely that a Persian physician named Rhazes discovered this substance, but as he spoke Arabic under Arab rule, the word remains of Arabic origin. It was introduced into Europe, together with the art of distillation and the substance itself, around the 12th century by various European authors who translated and popularized the discoveries of Islamic alchemists [1].

A popular theory, found in many dictionaries, is that it comes from 'DC-D al-ku%l, originally the name of very finely powdered antimony sulfide Sb2S3 used as an antiseptic and eyeliner. The powder is prepared by sublimation of the natural mineral stibnite in a closed vessel. According to this theory, the meaning of alkuhul would have been first extended to distilled substances in general, and then narrowed to ethanol. This conjectured etymology has been circulating in England since 1672 at least (OED).

However, this derivation is suspicious since the current Arabic name for alcohol, 'DC-HD al-ku%kl, does not derive from al-ku%l. The Qur'an, in verse 37:47, uses the word 'D:HD al-ghawl — properly meaning "spirit" or "demon" — with the sense "the thing that gives the wine its headiness". The word al-ghawl is also the origin of the English word "ghoul", and the name of the star Algol. This derivation would, of course, be consistent with the use of "spirit" or "spirit of wine" as synonymous of "alcohol" in most Western languages. (Incidentally, the etymology "alcohol" = "the devil" was used in the 1930s by the U.S. Temperance movement for propaganda purposes.)

According to the second theory, the popular etymology and the spelling "alcohol" would not be due to generalization of the meaning of al-ku%l, but rather to Western alchemists and authors confusing the two words al-ku%l and al-ghawl, which have indeed been transliterated in many different and overlapping ways.

Physical and chemical properties

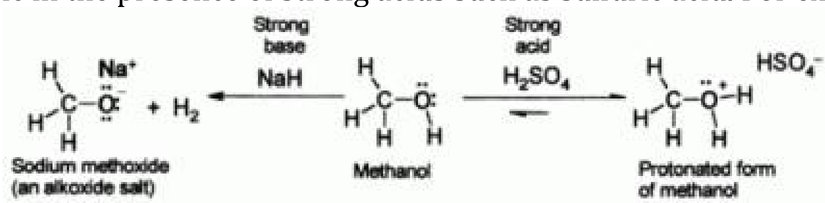
The hydroxyl group generally makes the alcohol molecule polar. Those groups can form hydrogen bonds to one another and to other compounds. Two opposing solubility trends in alcohols are: the tendency of the polar OH to promote solubility in water, and of the carbon chain to resist it. Thus, methanol, ethanol, and propanol are miscible in water because the hydroxyl group wins out over the short carbon chain. Butanol, with a four-carbon chain, is moderately soluble because of a balance between the two trends. Alcohols of five or more carbons (Pentanol and higher) are effectively insoluble because of the hydrocarbon chain's dominance.

Because of hydrogen bonding, alcohols tend to have higher boiling points than comparable hydrocarbons and ethers. The boiling point of the alcohol Ethanol is 78.29 °C, compared to 69 °C for the hydrocarbon Hexane (a common constituents of gasoline), and 34.6 °C for Diethyl ether. All simple alcohols are miscible in organic solvents. This hydrogen bonding means that alcohols can be used as protic solvents.

The lone pairs of electrons on the oxygen of the hydroxyl group also makes alcohols nucleophiles.

Alcohols, like water, can show either acidic or basic properties at the O-H group. With a pK***a*** of around 16-19 they are generally slightly weaker acids than water, but they are still able to react with strong bases such as sodium hydride or reactive metals such as sodium. The salts that result are called *alkoxides*, with the general formula RO- M+.

Meanwhile the oxygen atom has lone pairs of nonbonded electrons that render it weakly basic in the presence of strong acids such as sulfuric acid. For example, with methanol:



Alcohols can also undergo oxidation to give aldehydes, ketones or carboxylic acids, or they can be dehydrated to alkenes. They can react to form ester compounds, and they can (if activated first) undergo nucleophilic substitution reactions. For more details see the reactions of alcohols section below.

Toxicity

Alcohols often have an odor described as 'biting' that 'hangs' in the nasal passages. Ethanol in the form of alcoholic beverages has been consumed by humans since pre-historic times, for a variety of hygienic, dietary, medicinal, religious, and recreational reasons. While infrequent consumption of ethanol in small quantities may be harmless or even beneficial, larger doses result in a state known as drunkenness or intoxication (which may lead to a hangover the next day) and, depending on the dose and regularity of use, can cause acute respiratory failure or death and with chronic use has medical repercussions. Alcohol has also been known to be a catalyst for reckless behaviors that may have undesirable results, such as accidents, fighting, and unprotected sex. The LD50 of ethanol in rats 11,300 mg/kg.[2] This ratio would correspond to an 80kg (176.4lb) man drinking 65 shots of 80 proof alcohol, although the LD***50*** does not necessarily translate directly to humans.

Other alcohols are substantially more poisonous than ethanol, partly because they take much longer to be metabolized, and often their metabolism produces even more toxic substances. Methanol, or wood alcohol, for instance, is oxidized by alcohol dehydrogenase enzymes in the liver to the poisonous formaldehyde, which can cause blindness or death.

An effective treatment to prevent formaldehyde toxicity after methanol ingestion is to administer ethanol. Alcohol dehydrogenase has a higher affinity for ethanol, thus preventing methanol from binding and acting as a substrate. Any remaining methanol will then have

time to be excreted through the kidneys. Remaining formaldehyde will be converted to formic acid and excreted.

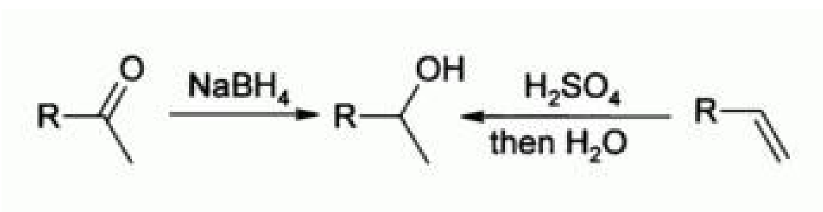
Preparation of alcohols

Laboratory

Several methods exist for the preparation of alcohols in the laboratory.

- Primary alkyl halides react with aqueous NaOH or KOH mainly to primary alcohols in nucleophilic aliphatic substitution. (Secondary and especially tertiary alkyl halides will give the elimination (alkene) product instead).
Aldehydes or ketones are reduced with sodium borohydride or lithium aluminium hydride (after an acidic workup). Another reduction by aluminumisopropylates is the Meerwein-Ponndorf-Verley reduction.
Alkenes engage in an acid catalysed hydration reaction using concentrated sulfuric acid as a catalyst which gives usually secondary or tertiary alcohols.
The hydroboration-oxidation and oxymercuration-reduction of alkenes are more reliable in organic synthesis.
Grignard reagents react with carbonyl groups to secondary and tertiary alcohols
Noyori asymmetric hydrogenation is the asymmetric reduction of ²-keto-esters

The formation of a secondary alcohol via reduction and hydration is shown:



Industrial

Industrially alcohols are produced in several ways:

- By fermentation using glucose produced from sugar from the hydrolysis of starch, in the presence of yeast and temperature of less than 37°C to produce ethanol. For instance the conversion of invertase to glucose and fructose or the conversion of glucose to zymase and ethanol.
By direct hydration using ethene or other alkenes from cracking of fractions of distilled crude oil. Uses a catalyst of phosphoric acid under high temperature and pressure.
Methanol is producted from water gas: It is manufactured from synthesis gas, where carbon monoxide and 2 equivalents of hydrogen gas are combined to produce methanol using a copper, zinc oxide and aluminium oxide catalyst at 250°C and a pressure of 50-100 atm.

Reactions of alcohols

Deprotonation

Alcohols can behave as weak acids, undergoing deprotonation. The deprotonation reaction to produce an alkoxide salt is either performed with a strong base such as sodium hydride or n-butyllithium, or with sodium or potassium metal.

2 R-OH + 2 NaH ’ 2 R-O-Na+ + H*2*‘ 2 R-OH + 2Na ’ 2R-ONa + H*2* E.g. 2 CH_3CH_2-OH + 2 Na ’ 2 CH*3*-CH*2*-ONa + H*2*

Water is similar in pK*a* to many alcohols, so with sodium hydroxide there is an equilibrium set up which usually lies to the left:

R-OH + NaOH <=> R-O-Na+ + H*2*O (equilibrium to the left)

It should be noted, though, that the bases used to deprotonate alcohols are strong themselves. The bases used and the alkoxides created are both highly moisture sensitive chemical reagents.

The acidity of alcohols is also affected by the overall stability of the alkoxide ion. Electron-withdrawing groups attached to the carbon containing the hydroxyl group will serve to stabilize the alkoxide when formed, thus resulting in greater acidity. On the other hand, the presence of electron-donating group will result in a less stable alkoxide ion formed. This will result in a scenario whereby the unstable alkoxide ion formed will tend to accept a proton to reform the original alcohol.

With alkyl halides alkoxides give rise to ethers in the Williamson ether synthesis.

Nucleophilic substitution

The OH group is not a good leaving group in nucleophilic substitution reactions, so neutral alcohols do not react in such reactions. However if the oxygen is first protonated to give ROH2+, the leaving group (water) is much more stable, and nucleophilic substitution can take place. For instance, tertiary alcohols react with hydrochloric acid to produce tertiary alkyl halides, where the hydroxyl group is replaced by a chlorine atom. If primary or secondary alcohols are to be reacted with hydrochloric acid, an activator such as zinc chloride is needed. Alternatively the conversion may be performed directly using thionyl chloride.[1]

Alcohols may likewise be converted to alkyl bromides using hydrobromic acid or phosphorus tribromide, for example:

$3\ R\text{-}OH + PBr_3$ ’ $3\ RBr + H_3PO_3$

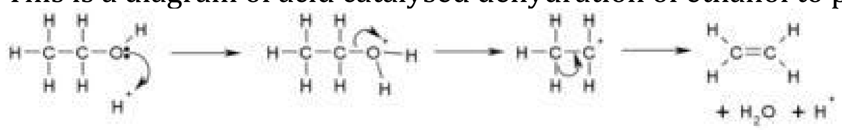
In the Barton-McCombie deoxygenation an alcohol is deoxygenated to an alkane with tributyltin hydride or a trimethylborane-water complex in a radical substitution reaction.

Dehydration

Alcohols are themselves nucleophilic, so ROH_2^+ can react with ROH to produce ethers and water in a dehydration reaction, although this reaction is rarely used except in the manufacture of diethyl ether.

More useful is the E1 elimination reaction of alcohols to produce alkenes. The reaction generally obeys Zaitsev's Rule, which states that the most stable (usually the most substituted) alkene is formed. Tertiary alcohols eliminate easily at just above room temperature, but primary alcohols require a higher temperature.

This is a diagram of acid catalysed dehydration of ethanol to produce ethene:



A more controlled elimination reaction is the Chugaev elimination with carbon disulfide and iodomethane.

Esterification

To form an ester from an alcohol and a carboxylic acid the reaction, known as Fischer esterification, is usually performed at reflux with a catalyst of concentrated sulfuric acid:

$R\text{-}OH + R'\text{-}COOH$ ’ $R'\text{-}COOR + H_2O$

In order to drive the equilibrium to the right and produce a good yield of ester, water is usually removed, either by an excess of H_2SO_4 or by using a Dean-Stark apparatus. Esters may also be prepared by reaction of the alcohol with an acid chloride in the presence of a base such as pyridine.

Other types of ester are prepared similarly- for example tosyl (tosylate) esters are made by reaction of the alcohol with p-toluenesulfonyl chloride in pyridine.

Oxidation

Primary alcohols generally give aldehydes or carboxylic acids upon oxidation, while secondary alcohols give ketones. Traditionally strong oxidants such as the dichromate ion or potassium permanganate are used, under acidic conditions, for example:

$3\ CH_3\text{-}CH(\text{-}OH)\text{-}CH_3 + K_2Cr_2O_7 + 4\ H_2SO_4$ ’ $3\ CH_3\text{-}C(=O)\text{-}CH_3 + Cr_2(SO_4)_3 + K_2SO_4 + 7\ H_2O$

Frequently in aldehyde preparations these reagents cause a problem of over-oxidation to the carboxylic acid. To avoid this, other reagents such as PCC, Dess-Martin periodinane, 2-Iodoxybenzoic acid, TPAP or methods such as Swern oxidation and Corey-Kim oxidation are now preferred. In the Guerbet reaction aliphatic alcohols dimerize with an initial oxidation step.

Alcohols with a methyl group attached to the alcohol carbon can also undergo a haloform reaction (such as the iodoform reaction) in the presence of the halogen and a base such as sodium hydroxide.

Tertiary alcohols resist oxidation, but can be oxidised by reagents such as 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

Boric acid

Boric acid

General

Other names Orthoboric acid, Boracic acid, Sassolite, Optibor®, Borofax®

Molecular formula H_3BO_3

Molar mass 61.832 g/mol

Appearance White crystalline liquid

CAS number [10043-35-3]

Properties

Density and phase 1.435 g/cm^3, solid.

Solubility in water 5.7 g/100 ml (25°C)

Melting point 169°C decomp.

Related compounds Boron trioxide, Borax

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

Boric acid, also called *boracic acid* or *orthoboric acid*, is a mild acid often used as an antiseptic, insecticide, flame retardant, in nuclear power plants to control the fission rate of uranium, and as a precursor of other chemical compounds. It exists in the form of colorless crystals or a white powder and dissolves in water. It has the chemical formula H_3BO_3, sometimes written $B(OH)_3$. When occurring as a mineral, it is called sassolite.

Preparation

Boric acid is produced mainly from borate minerals by the reaction with sulfuric acid. The largest source of borates in the world is an open-pit mine in Death Valley, California, USA.

Properties

Boric acid was first prepared by Wilhelm Homberg (1652-1715) from borax, by the action of mineral acids, and was given the name sal sedativum Hombergi. The presence of boric acid or its salts has been noted in sea-water, whilst it is also said to exist in plants and especially in almost all fruits (A. H. Allen, Analyst, 1904, 301). The free acid is found native in certain volcanic districts such as Tuscany, the Lipari Islands and Nevada, issuing mixed with steam from fissures in the ground; it is also found as a constituent of many minerals (borax, boracite, boronatrocaicite and colemanite).Boric acid is soluble in boiling water. When heated above 170°C it dehydrates, forming *metaboric acid* HBO_2. Metaboric acid is a white, cubic crystalline solid and is only slightly soluble in water. It melts at about 236°C, and when heated above about 300°C further dehydrates, forming *tetraboric acid* or *pyroboric acid*, $H_2B_4O_7$. Boric acid can refer to any of these compounds. Further heating leads to boron trioxide.

Boric acid does not dissociate in aqueous solution, but is acidic due to its interaction with water molecules:

$B(OH)_3 + H_2O$ Ì $B(OH)_4 + H^+$ $K_a = 5.8x10^{10}$ L/mol; $pK_a = 9.24$.

Polyborate anions are formed at pH 7–10 if the boron concentration is higher than about 0.025 mol/L. The best known of these is the *tetraborate* ion, found in the mineral borax:

$4B(OH)_4 + 2H^+$ Ì $B_4O_7^2 + 9H_2O$

Uses

It can be used as an antiseptic for minor burns or cuts and is sometimes used in dressings or salves or is applied in a very dilute solution as an eye wash. It is poisonous if taken internally or inhaled, although it is generally not considered to be much more toxic than table salt (based on its mammal LD50 rating of 2660mg/kg body mass).

Boric acid can be used to treat yeast and fungal infections such as candidiasis (vaginal yeast infections) by filling gelcaps with boric acid powder and inserting two into the vaginal canal at bedtime for three to four nights in a row. It is also used as prevention of athlete's foot, by inserting powder in the socks or stockings, and in solution can be used to treat some kinds of otitis externa (ear infection) in both humans and animals. The preservative in urine sample bottles (red cap) in the UK is Boric acid.

It is often used as a relatively nontoxic insecticide, for killing cockroaches, termites, fire ants, fleas, and many other insects. It can be used directly in powdered form for fleas and cockroaches, or mixed with sugar or grape jelly for ants. It is also a component of many commercial insecticides. In this use, especially in the case of cockroaches, the boric acid in the form of a powder is applied to areas frequented by the insects. The lightweight particles cling to the legs of the insects and eventually cause fatal chemical burns. Boric acid for this use in residential apartments is sold commercially in urban areas afflicted with cockroaches.

Boric acid is used in nuclear power plants to slow down the rate at which fission is occurring. Fission chain reactions are generally driven by the amount of neutrons present (as products from previous fissions). Boron has a high cross-section for absorption of neutrons and is therefore dissolved into the primary coolant which circulates through the reactor. By changing the concentration of boric acid in the water, fission can be regulated. Boron is also dissolved into the spent fuel pools containing used uranium rods. The concentration is high enough to keep fissions at a minimum.

In the jewelry industry, boric acid is often used in combination with denatured alcohol to reduce surface oxidation and firescale from forming on metals during annealing and soldering operations.

Borates including boric acid have been used since the time of the Greeks for cleaning, preserving food, and other activities.

Lithium boric acid is the lithium salt of boric acid and is used in the laboratory as buffer for gel. TBE buffer is widely used for the electrophoresis of nucleic acids and has a higher buffer capacity than a TAE Buffer. It can be used for DNA and RNA polyacrylamide and agarose gel electrophoresis.

It is used in pyrotechnics to prevent the amide-forming reaction between aluminum and nitrates. A small amount of boric acid is added to the composition to neutralize alkaline amides that can react with the aluminum.

It is also used in India and across the world to dust down Carrom Boards to decrease friction and increase speed of play.

Calcium hypochlorite

Systematic name Calcium hypochlorite

Other names HTH

Molecular formula $Ca(ClO)_2$

Molar mass 143.1 g/mol

Calcium hypochlorite is a chemical compound with formula $Ca(ClO)_2$. It is widely used for water treatment and as a bleaching agent (bleaching powder). This chemical is considered to be relatively stable and has greater available chlorine than sodium hypochlorite (liquid bleach).

Preparation

It is manufactured using the calcium process and sodium process. Or it can be prepared by the action of slaked lime on chlorine:

$Ca(OH)_2 + Cl_2$ ’ $Ca(OCl)_2 + H_2$

Bleaching powder is actually a mixture of calcium hypochlorite $Ca(OCl)_2$ and the basic chloride $CaCl_2$, $Ca(OH)_2$, H_2O with some slaked lime, $Ca(OH)_2$.

Properties

It is a yellow white solid which has a strong smell of chlorine. Calcium hypochlorite is not highly soluble in water. For that reason it should preferably be used in soft to middle hard water. There are two types of calcium hypochlorite - a dry form and a hydrated form. The hydrated form is safer to handle.

Calcium hypochlorite reacts with carbon dioxide to form calcium carbonate and release chlorine:

$Ca(OCl)_2 + CO_2$ ’ $CaCO_3 + Cl_2$

Calcium hypochlorite reacts with hydrochloric acid to form calcium chloride:

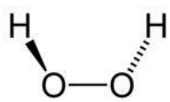
$Ca(OCl)_2 + 2\ HCl$ ’ $CaCl_2 + H_2O + Cl_2$

Uses

Calcium hypochlorite is used for the disinfection of drinking water or swimming pool water. For use in outdoor swimming pools, calcium hypochlorite can be used as a sanitiser in combination with a cyanuric acid stabiliser. The stabiliser will reduce the loss of chlorine because of UV radiation.

Calcium hypochlorite (known as 'bleaching powder') is also used for bleaching cotton and linen and used in the manufacture of chloroform.

Hydrogen peroxide



Systematic name Dihydrogen dioxide

Related compounds water, ozone, hydrazine

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

Hydrogen peroxide (H_2O_2) is a very pale blue liquid which appears colourless in a dilute solution, slightly more viscous than water. It has strong oxidizing properties and is therefore a powerful bleaching agent that has found use as a disinfectant, as an oxidizer, and in rocketry (particularly in high concentrations as high-test peroxide (HTP) as a monopropellant), and in bipropellant systems.

History

Hydrogen peroxide was first isolated in 1818 by Louis Jacques Thénard by reacting barium peroxide with nitric acid. An improved version of this process used hydrochloric acid, followed by sulfuric acid to precipitate the barium chloride byproduct. Thenard's process was used from the end of the 19th century until the middle of the 20th century. [1] Modern manufacture methods are discussed below.

Uses

Industrial applications

About 50% of the world's production of hydrogen peroxide in 1994 was used for pulp- and paper-bleaching. Other bleaching applications are becoming more important as

hydrogen peroxide is seen as an environmentally-benign alternative to chlorine-based bleaches.

Other major industrial applications for hydrogen peroxide include the manufacture of sodium percarbonate and sodium perborate, used as mild bleaches in laundry detergents. It is used in the production of certain organic peroxides such as dibenzoyl peroxide, used in polymerisations and other chemical processes. Hydrogen peroxide is also used in the production of epoxides such as propylene oxide. Reaction with carboxylic acids produces a corresponding "per-acid". Peracetic acid and meta-chloroperoxybenzoic acid (commonly abbreviated mCPBA) are prepared from acetic acid and meta-chlorobenzoic acid, respectively. The latter is commonly reacted with alkenes to give the corresponding epoxide.

Domestic uses

Diluted H_2O_2 (around 5%) is used to bleach human hair, hence the phrases *peroxide blonde* and *bottle blonde*. It can absorb into skin upon contact and create a local skin capillary embolism which appears as a temporary whitening of the skin. It whitens skeletons that are to be put on display. 3% H2O2 is used medically for cleaning wounds, removing dead tissue, or as an oral debriding agent. Most over-the-counter peroxide solutions are not, however, suitable for ingestion.

The Food and Drug Administration (FDA) has classified hydrogen peroxide as a Low Regulatory Priority (LRP) drug for use in controlling fungus on fish and fish eggs.

Some gardeners and hydroponics implementers have professed the value of hydrogen peroxide in their watering solutions. They claim its spontaneous decomposition releases oxygen to the plant that can enhance root development and also help treat root rot, which is cellular root death due to lack of oxygen. Laboratory tests conducted by fish culturists in recent years have demonstrated that common household hydrogen-peroxide can be used safely to provide oxygen for small fish. Citation Reference Hydrogen-peroxide releases oxygen by decomposition when it is exposed to catalysts.

Hydrogen peroxide is increasingly popular for the treatment of hydrogen sulfide and iron. Catalytic carbon and redox media perform well with hydrogen peroxide pretreatment. Generally 90% of the reaction between hydrogen peroxide and hydrogen sulfide takes place within 10 to 15 minutes, with the balance reacting in an additional 20 to 30 minutes. The sulfur in hydrogen sulfide H_2S) is in the -2 state. In a neutral solution, hydrogen peroxide will oxidize hydrogen sulfide to elemental sulfur via the following reaction: 8 H_2S(g) + 8 H_2O_2(aq) ’ S_8(s) + 16 H_2O(l)

The reaction is slow but may be catalyzed by metal ions. To be more specific for doses of chemical feed levels for oxidation of iron, manganese and hydrogen sulfide in domestic water supplies, here are some figures: Iron: For each ppm Fe feed = 0.3 - 0.5 ppm, 20 minutes Manganese: For each ppm Mn feed = 0.8 - 1.0 ppm, 20 minutes Hydrogen Sulfide: For each ppm H2S feed = 1.0 - 1.5 ppm, 30 minutes (all above figures are for minimum retention time). When more than one constituent is to be oxidized (i.e. iron & H_2S) add the above values to determine the total ppm feed needed to oxidize two or more.

Hydrogen peroxide is a strong oxidizer effective in controlling sulfide and organic related odors in wastewater collection and treatment systems. It is typically applied to a wastewater

system most frequently where there is a retention time of less than five hours and at least 30 minutes prior to the point where the hydrogen sulfide is released. Hydrogen peroxide will oxidize the hydrogen sulfide present and in addition promote bio-oxidation of organic odors. Hydrogen peroxide decomposes to oxygen and water adding dissolved oxygen to the system thereby reducing Biological Oxygen Demand (BOD).

Commercial peroxide, as bought at the drugstore in a 2.5%-3% solution, can be used to remove bloodstains from carpets and clothing. If a few tablespoons of peroxide are poured onto the stain, they will bubble up in the area of the blood. After a few minutes the excess liquid can be wiped up with a cloth or paper towel and the stain will be gone. Care should be taken, however, as hydrogen peroxide will bleach or discolor many fabrics.

Hydrogen peroxide is used in glow sticks as an oxidising agent. It reacts with phenyl oxalate ester to form an unstable CO_2 dimer which in turn causes an added dye to reach an excited state, the latter relaxing to release photons of light.

Storage

Small quantities of many different concentrations and grades can be legally stored and used with few regulations.

Hydrogen peroxide should be stored in a container made from a material that doesn't react with the chemical. Numerous materials and processes are available, and these vary based on the concentration and grade (purity) of the hydrogen peroxide. In general, it is an oxidizer and should be stored away from fuel sources and sources of catalytic contamination. Because oxygen is formed during the natural decomposition of the peroxide, the resulting increase in pressure can cause a glass container to break. Therfore, H_2O_2 should be stored in vented plastic containers.

Use as propellant

H_2O_2 can be used either as a monopropellant (not mixed with fuel) or as the oxidizer component of a bipropellant rocket. Use as a monopropellant takes advantage of the decomposition of 70–98+% concentration hydrogen peroxide into steam and oxygen. The propellant is pumped into a reaction chamber where a catalyst (usually a silver or platinum screen) triggers decomposition, and the hot (>600 °C) oxygen/steam produced is used directly for thrust. H2O2 monopropellant produces a maximum specific impulse (Isp) of 161 s (1.6 kN·s/kg), which makes it a low-performance monopropellant. Compared to hydrazine, peroxide is less toxic, but it is also much less powerful. The famous Bell Rocket Belt used hydrogen peroxide monopropellant.

As a bipropellant, H_2O_2 is decomposed to burn a fuel as an oxidizer. Specific impulses as high as 350 s (3.5 kN·s/kg) can be achieved, depending on the fuel. Peroxide used as an oxidizer gives a somewhat lower I_{sp} than liquid oxygen, but is dense, storable, noncryogenic and can be more easily used to drive gas turbines to give high pressures. It also can be used for regenerative cooling of rocket engines. Peroxide was used very successfully as an oxidizer for early World-War-II era German rockets, and for the low-cost British launchers, Black Knight and Black Arrow.

In the 1940s and 1950s, the Walter turbine used hydrogen peroxide for use in submarines while submerged; it was found to be too noisy and maintenance-demanding compared to the conventional diesel-electric power system. Some torpedoes used hydrogen peroxide as oxidizer or propellant, but this use has been discontinued by most navies for safety reasons. Hydrogen peroxide leaks were blamed for the sinkings of HMS Sidon and the Russian submarine Kursk. It was discovered, for example, by the Japanese Navy in torpedo trials, that the concentration of H_2O_2 in right-angle bends in HTP pipework can often lead to explosions in submarines and torpedoes.

While its application as a monopropellant for large engines has waned, small thrusters for attitude control that run on hydrogen peroxide are still in use on some satellites, and provide benefits on the spacecraft, making it easier to throttle and safer loading and handling of fuel before launch (as compared to hydrazine monopropellant). However, hydrazine is a more popular monopropellent in spacecraft because of its higher specific impulse and lower rate of decomposition.

Recently, H2O2/propylene as an approach to inexpensive Single Stage To Orbit has been proposed; this involves a main fuel tank containing propylene, with a bladder floating in it containing the H2O2. This combination offers 15% superior ISP to O2/RP4 (a kerosene used as rocket propellant), avoiding the need for turbines, cryogenic storage or hardware, and greatly reduced cost for the construction of the booster; the potential of this and other alternate systems is discussed in some detail at Dunn Engineering which is offered as a citation.

Therapeutic use

Hydrogen peroxide has been used as an antiseptic and anti-bacterial agent for many years. While its use has decreased in recent years due to the popularity of better-smelling and more readily-available over the counter products, it is still used by many hospitals, doctors and dentists in sterilising, cleaning and treating everything from floors to Root canal procedures.

Recently, alternative medical practitioners have advocated administering doses of hydrogen peroxide intravenously in extremely low (less than one percent) concentrations for hydrogen peroxide therapy — a controversial alternative medical treatment for cancer. However, according to the American Cancer Society, "there is no scientific evidence that hydrogen peroxide is a safe, effective or useful cancer treatment." They advise cancer patients to "remain in the care of qualified doctors who use proven methods of treatment and approved clinical trials of promising new treatments." [2] Internal use of hydrogen peroxide has a history of causing fatal blood disorders, and its recent use as a therapeutic treatment has been linked to several deaths.[3],[4]

Hydrogen peroxide is GRAS (Generally Recognised As Safe) as an antimicrobial agent, an oxidizing agent and more by the US Food and Drug Administration.[5] Hydrogen peroxide can also be used as a toothpaste when mixed with correct quantities of baking soda and salt.[6] Like benzoyl peroxide, hydrogen peroxide is also sometimes used in the treatment of acne.

Hydrogen peroxide is also used as an emetic in veterinary practice.[7]

Physical properties

Hydrogen peroxide adopts a "skewed" shape, due to repulsion between the lone pairs on the oxygen atoms. Despite the fact that the O-O bond is a single bond, the molecule has a remarkably high barrier to complete rotation of 29.45 kJ/mol (compared with 12.5 kJ/mol for the rotational barrier of ethane). The increased barrier is also attributed to lone-pair lone-pair repulsion. The bond angles are affected by hydrogen bonding, which is relevant to the structural difference between gaseous and crystalline forms; indeed a wide range of values is seen in crystals containing molecular H_2O_2.

Chemical properties

H_2O_2 is one of the most powerful oxidizers known -- stronger than chlorine, chlorine dioxide, and potassium permanganate. And through catalysis, H_2O_2 can be converted into hydroxyl radicals (.OH) with reactivity second only to fluorine.

Oxidant - Oxidation potential, V

Fluorine 3.0

Hydroxyl radical 2.8

Ozone **2.1**

Hydrogen peroxide 1.8

Potassium permanganate **1.7**

Chlorine dioxide 1.5

Chlorine 1.4

Hydrogen peroxide can decompose spontaneously into water and oxygen. It usually acts as an oxidizing agent, but there are many reactions where it acts as a reducing agent, releasing oxygen as a by-product. It also readily forms both inorganic and organic peroxides.

Decomposition

Hydrogen peroxide often decomposes (disproportionates) exothermically into water and oxygen gas spontaneously:

2 H_2O_2 ’ 2 H_2O + O_2 + Energy

This process is very favorable; it has a ”Ho of 98.2 kJ/mol and a ”Go of 119.2 kJ/mol and a ”S of 70.5 J/mol K. The rate of decomposition is dependent on the temperature and

concentration of the peroxide, as well as the pH and the presence of impurities and stabilizers. Hydrogen peroxide is incompatible with many substances that catalyse its decomposition, including most of the transition metals and their compounds. Common catalysts include manganese dioxide, potassium permanganate, and silver. The same reaction is catalysed by the enzyme catalase, found in the liver, whose main function in the body is the removal of toxic byproducts of metabolism and the reduction of oxidative stress. The decomposition occurs more rapidly in alkali, so acid is often added as a stabilizer.

Spilling high concentration peroxide on a flammable substance can cause an immediate fire fueled by the oxygen released by the decomposing hydrogen peroxide. High-strength peroxide (also called high-test peroxide, or HTP) must be stored in a vented container to prevent the buildup of oxygen gas, which would otherwise lead to the eventual rupture of the container. Any container must be made of a compatible material such as PTFE, polyethylene, stainless steel, or aluminium and undergo a cleaning process (passivation) to remove all contamination prior to the introduction of peroxide. (Note that while compatible at room temperature, polyethylene can explode with peroxide in a fire.)

In the presence of certain catalysts, such as Fe^{2+} or Ti^{3+}, the decomposition may take a different path, with free radicals such as HO· (hydroxyl) and HOO· being formed. A combination of H_2O_2 and Fe^{2+} is known as Fenton's reagent.

Redox reactions

In aqueous solution, hydrogen peroxide can oxidize or reduce a variety of inorganic ions. When it acts as a reducing agent, oxygen gas is also produced. In acid solution Fe^{2+} is oxidized to Fe^{3+},

$2\,Fe^{2+}(aq) + H_2O_2 + 2\,H^{+}(aq)$ ’ $2\,Fe^{3+}(aq) + 2H_2O(l)$

and sulfite (SO_3^2) is oxidized to sulfate (SO_4^2). However, potassium permanganate is reduced to Mn^{2+} by acidic H_2O_2. Under alkaline conditions, however, some of these reactions reverse; Mn^{2+} is oxidized to Mn^{4+} (as MnO_2), yet Fe^{3+} is reduced to Fe^{2+}.

$2\,Fe^{3+} + H_2O_2 + 2\,OH$ ’ $2\,Fe^{2+} + 2\,H_2O + O_2$

Hydrogen peroxide is frequently used as an oxidising agent in organic chemistry. One application is for the oxidation of thioethers to sulfoxides. For example, methyl phenyl sulfide was oxidised to methyl phenyl sulfoxide in 99% yield in methanol in 18 hours (or 20 minutes using a $TiCl_3$ catalyst):

$Ph\text{-}S\text{-}CH_3 + H_2O_2$ ’ $Ph\text{-}S(O)\text{-}CH_3 + H_2O$

Alkaline hydrogen peroxide is used for epoxidation of electron-deficient alkenes such as acrylic acids, and also for oxidation of alkylboranes to alcohols, the second step of hydroboration-oxidation.

Formation of peroxide compounds

Hydrogen peroxide is a weak acid, and it can form hydroperoxide or peroxide salts or derivatives of many metals. For example, with aqueous solutions of chromic acid (CrO_3), it can form an unstable blue peroxide $CrO(O_2)_2$. It can also produce peroxoanions by reaction with anions; for example, reaction with borax leads to sodium perborate, a bleach used in laundry detergents:

$Na_2B_4O_7 + 4\ H_2O_2 + 2\ NaOH \rightarrow 2\ Na_2B_2O_4(OH)_4 + H_2O$

H_2O_2 converts carboxylic acids (RCOOH) into peroxy acids (RCOOOH), which are themselves used as oxidizing agents. Hydrogen peroxide reacts with acetone to form acetone peroxide, and it interacts with ozone to form hydrogen trioxide. Reaction with urea produces carbamide peroxide, used for whitening teeth. An acid-base adduct with triphenylphosphine oxide is a useful "carrier" for H_2O_2 in some reactions.

Hydrogen peroxide reacts with ozone to form trioxidane.

Alkalinity

Hydrogen peroxide is a much weaker base than water, but it can still form adducts with very strong acids. The superacid HF/SbF_5 forms unstable compounds containing the $[H_3O_2]^+$ ion.

Manufacture

Hydrogen peroxide is manufactured today almost exclusively by the autoxidation of 2-ethyl-9,10-dihydroxyanthracene to 2-ethylanthraquinone and hydrogen peroxide using oxygen from the air. The anthraquinone derivative is then extracted out and reduced back to the dihydroxy compound using hydrogen gas in the presence of a metal catalyst. The overall equation for the process is deceptively simple:

$H_2 + O_2 \rightarrow H_2O_2$

However the economics of the process depend on effective recycling of the quinone and extraction solvents, and of the hydrogenation catalyst.

Formerly inorganic processes were used, employing the electrolysis of an aqueous solution of sulfuric acid or acidic ammonium bisulfate (NH_4HSO_4), followed by hydrolysis of the peroxydisulfate $((SO_4)_2)^{2}$ which is formed.

In 1994, world production of H_2O_2 was around 1.9 million tonnes, most of which was at a concentration of 70% or less. In that year bulk 30% H_2O_2 sold for around US \$0.54 per kg, equivalent to US \$1.50 per kg (US \$0.68 per lb) on a "100% basis".

Concentration

Hydrogen peroxide works best as a propellant in extremely high concentrations. At concentrations above approximately 67%, decomposed hydrogen peroxide will produce superheated vapors which can then be used to generate thrust, power, or work. Normal

propellant grade concentrations vary from 70 to 98% with common grades of 70, 85, 90, and 98%. Many of these grades and variations are described in detail in the United States propellant specification number MIL-P-16005 Revision F, which is currently available. The available suppliers of high concentration propellant grade hydrogen peroxide are generally one of the large commercial companies which make other grades of hydrogen peroxide; including Solvay Interox, FMC, and Degussa. Other companies which have made propellant grade hydrogen peroxide in the recent past include Air Liquide and DuPont. Note that DuPont recently sold its hydrogen peroxide manufacturing business to Degussa.

Propellant grade hydrogen peroxide is available to qualified buyers. Typically this chemical is only sold to commercial companies or government institutions which have the ability to properly handle and utilize the material.

Non-professionals have purchased 70% or lower concentration hydrogen peroxide (the remaining 30% is water with traces of impurities and stabilizing materials, such as tin salts, phosphates, nitrates, and other chemical additives), and increased its concentration themselves - a potentially extremely dangerous practice that should not be encouraged. Many amateurs try distillation, but this is extremely dangerous with hydrogen peroxide; peroxide vapor can ignite or detonate depending on specific combinations of temperature and pressure. In general any boiling mass of high concentration hydrogen peroxide at ambient pressure will produce vapor phase hydrogen peroxide which can detonate. This hazard is mitigated, but not entirely eliminated with vacuum distillation. Vacuum distillation of propellant grade hydrogen peroxide is still hazardous and is best done by qualified laboratories or companies. Other approaches for concentrating hydrogen peroxide are sparging and fractional crystallization.

High concentration hydrogen peroxide is readily available in 70, 90, and 98% concentrations in sizes of 1 gallon, 30 gallon, and bulk tanker truck volumes. Propellant grade hydrogen peroxide is being used on current military systems and is in numerous defense and aerospace research and development programs. Many privately funded rocket companies are using hydrogen peroxide, notably Blue Origin. Some amateur groups have expressed interest in manufacturing their own peroxide, for their use and for sale in small quantities to others. The production of hydrogen peroxide by amateurs is potentially dangerous to both the producers of the chemical, persons in the vicinity of the chemical, and users of the chemical.

Hazards

Hydrogen peroxide, either in pure or diluted form, can pose several risks:

- Above roughly 70% concentrations, hydrogen peroxide can give off vapor that can detonate above 70 °C (158 °F) at normal atmospheric pressure. This can then BLEVE the remaining liquid. Distillation of hydrogen peroxide at normal pressures is thus highly dangerous, and must be avoided.
- Hydrogen peroxide vapors can form sensitive contact explosives with hydrocarbons such as greases. Hazardous reactions ranging from ignition to explosion have been reported with alcohols, ketones, carboxylic acids

(particularly acetic acid), amines and phosphorus. The saying is 'peroxides kill chemists'.

- Hydrogen peroxide, if spilled on clothing (or other flammable materials), will preferentially evaporate water until the concentration reaches sufficient strength, then clothing will spontaneously ignite. Leather generally contains metal ions from the tanning process and will often catch fire almost immediately.[8]
- Concentrated hydrogen peroxide (>50%) is corrosive, and even domestic-strength solutions can cause irritation to the eyes, mucous membranes and skin. Swallowing hydrogen peroxide solutions is particularly dangerous, as decomposition in the stomach releases large quantities of gas (10 times the volume of a 3% solution) leading to internal bleeding. Severe pulmonary irritation by inhalation over 10%.

Hydrogen peroxide is naturally produced as a byproduct of oxygen metabolism, and virtually all organisms possess enzymes known as peroxidases, which apparently harmlessly catalytically decomposes low concentrations of hydrogen peroxide to water and oxygen (see Decomposition above).

In one incident, several people were injured after a hydrogen peroxide spill on board Northwest Airlines Flight 957 because they mistook it for water.

For more information on the risks of working with this chemical, consult an MSDS. It reacts to make water and oxygen gas.

Listerine

Listerine is a brand name for antiseptic mouthwash, named after the English physician Joseph Lister (father of modern antiseptics) who had performed the first antiseptic surgery ever in 1865. Its medicinal taste is palliated slightly by a sweet flavor. Its slogan is "Kills germs that cause bad breath", though halitosis can return after use, even if nothing "extra" is placed in the mouth. This happens because saliva washes away the product, allowing the body's natural bacteria to repopulate the area.

Listerine is one of the most popular mouthwashes sold in the U.S. It is currently manufactured and distributed by Pfizer Inc, however, subject to regulatory approvals by the end of 2006, Johnson & Johnson will acquire the Listerine brand. Procter & Gamble's Scope is its main competitor.

The active ingredients are menthol, thymol, methyl salicylate, and eucalyptol, all of which are structural isomers. Ethanol or grain alcohol is present in concentrations between 21 and 26% w/v. At the concentrations in Listerine, ethanol per se does not have antimicrobial activity but rather serves to dissolve the active ingredients and to facilitate the penetration of the active ingredients into dental plaque.

Listerine has therapeutic uses that contribute to oral health when used regularly as an adjunct to mechanical oral hygiene procedures (toothbrushing and flossing). In clinical studies it has been shown that using Listerine regularly can reduce an additional 52% more plaque than merely brushing and flossing. Listerine was the first over-the-counter mouthwash to receive the American Dental Association's Seal of Acceptance for helping to control dental plaque and gingivitis. In addition, an FDA Advisory Panel has recommended that the active ingredients in Listerine be classified as Category I (safe and effective) for antiplaque and antigingivitis activity.

The Listerine brand name is also used on brands of toothpaste and on PocketPaks, a minty, dissolvable strip intended to instantly wash and refresh the mouth. In the late summer of 2005, Listerine began selling PocketMist, which is a breath-freshener in spray form.

History

First formulated by Dr Joseph Lawrence and Jordan Wheat Lambert in 1879 as a surgical antiseptic, it was given to dentists for oral care in 1895 and became the first over-the-counter mouthwash sold in the United States in 1914.

According to Freakonomics (p. 91),

Listerine was invented in the 19th century as a powerful surgical antiseptic. It was later sold, in a distilled form, as a floor cleaner and a cure for gonorrhea. But it wasn't a runaway success until the 1920s, when it was pitched as a solution for "chronic halitosis", the faux medical term that the Listerine advertising group created in 1921 to describe bad breath. By naming and thus creating a medical condition for which consumers now felt they needed a cure, Listerine created a market for their mouthwash. Until that time, bad breath was not conventionally considered a catastrophe, but Listerine's ad campaign changed that. As the advertising scholar James B. Twitchell writes, "Listerine did not make mouthwash as much as it made halitosis." Listerine's new ads featured forlorn young women and men, eager for marriage but turned off by their mate's rotten breath. "Can I be happy with him in spite of that?" one maiden asked herself. In just seven years, the company's revenues rose from $115,000 to more than $8 million.

From 1921 until the mid-1970s Listerine was also marketed as a preventive and remedy for colds and sore throats. In 1976, the Federal Trade Commission ruled that these claims were misleading, and that Listerine had "no efficacy" at either preventing or alleviating the symptoms of sore throats and colds. Warner-Lambert was ordered to stop making the claims, and to include in the next $10.2 million dollars' of Listerine ads a specific mention that "contrary to prior advertising, Listerine will not help prevent colds or sore throats or lessen their severity."

Listerine was packaged in a glass bottle inside a cardboard tube for nearly 80 years before the first revamps were made to the brand; in 1992, Cool Mint Listerine was introduced in addition to the regular Antiseptic formula, and in 1994, both brands were introduced in plastic bottles for the first time. In 2002, FreshBurst was added, then in 2003 Natural Citrus and in 2004, the ill-fated Cinnamon was released. In 2006 a new addition to the "less intense" variety, Vanilla Mint, was released. Currently, seven different kinds of Listerine are on the market in the U.S. and abroad: Original, Cool Mint, FreshBurst, Natural Citrus, Vanilla Mint, Advanced with Tartar Control, and Whitening. The most recent addition is the whitening formula.

Safety

There is no evidence that its properties as a solvent, mainly from the 26.9% (in regular Listerine) alcohol, cause an easier reception of carcinogens. In other words, repeated use of Listerine does not increase the risk of oral cancer. Both the American Dental Association (ADA) and the United States National Cancer Institute (NCI) agree that the alcohol contained in antiseptic mouthrinse is safe and not a factor in oral cancers. Specific study reviews and results can be found in clinical reports by J.G. Elmore and R.I. Horowitz ["Oral cancer and mouthwash use: Evaluation of the epidemiologic evidence." Otolaryngol Head Neck Surg. 1995;1(113):253–261] and Mashburg et al. ["A Study of the relationship between mouthwash use and oral and pharyngeal cancer." JADA, 1985.] which summarize that alcohol-containing mouth rinses are not associated with oral cancer.

Trivia

In the mid-1990s, Scope listed Rosie O'Donnell as the least-kissable celebrity in the U.S. She teamed up with Listerine to give money to charity every time she kissed someone on her talk show; this provided positive publicity for Listerine and harsh publicity for Scope, which O'Donnell disparaged on her show.

The song "Germfree Adolecents" by the 1970's punk rock group X-Ray Spex has a lyric that has often been misheard. Some will hear "Rinse your mouth with Listerine" when the lyric is actually "Rinse your mouth with glycerine".

Naphthalene

Naphthalene

Chemical name Naphthalene

Other names Tar Camphor, White Tar, Moth Flakes

Chemical formula $C_{10}H_8$

SMILES C1(C=CC=C2)=C2C=CC=C1

Molar mass 128.17052 g/mol

Appearance White solid crystals/flakes, strong odor of coal tar

CAS number 91-20-3

Properties

Density 1.14 g/cm^3

Solubility in water Insoluble in water

Melting point 80.5 °C

Boiling point 218 °C

Hazards

MSDS External MSDS

Main hazards Flammable, sensitizer, possible carcinogen. Dust can form explosive mixtures with air

Flash point 79 - 87 °C

Autoignition temperature 525 °C

R/S statement R: 20, 21, 22, 36, 37, 38, 43, 45 S: 16, 26, 36, 37, 39, 45

RTECS number QJ0525000

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

Naphthalene (not to be confused with naphtha) (also known as *naphthalin*, *naphthaline*, *tar camphor*, *white tar*, *albocarbon*, or *naphthene*), is a crystalline, aromatic, white, solid hydrocarbon, best known as the primary ingredient of mothballs. Naphthalene is volatile, forming a flammable vapor. Its molecules consist of two fused benzene rings. It is manufactured from coal tar, and converted to phthalic anhydride for the manufacture of plastics, dyes and solvents. It is also used as an antiseptic and insecticide, especially in mothballs. p-Dichlorobenzene is now often used instead of naphthalene as a mothball substitute. Naphthalene easily sublimates at room temperature.

History

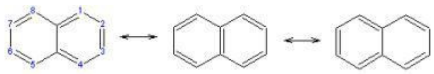
In 1819-1820, at least two chemists reported a white solid with a pungent odor derived from the distillation of coal tar. In 1821, John Kidd described many of this substance's properties and the means of its production, and proposed the name naphthaline, as it had been derived from a kind of naphtha (a broad term encompassing any volatile, flammable liquid hydrocarbon mixture, including coal tar).

Naphthaline's empirical formula, C_5H_4, was determined by Michael Faraday in 1826. The structure of two fused benzene rings was proposed by Emil Erlenmeyer in 1866, and confirmed by Carl Graebe three years later.

Structure and reactivity

A naphthalene molecule is composed of two fused benzene rings. (In organic chemistry, rings are fused if they share two or more atoms). Accordingly, naphthalene is classified as a benzenoid polycyclic aromatic hydrocarbon (PAH). Naphthalene has three resonance structures, which are shown in the drawing below. Naphthalene has two sets of equivalent hydrogens. The alpha positions are positions 1, 4, 5, and 8 on the drawing below. The beta positions are positions 2, 3, 6, and 7.

Unlike benzene, the carbon-carbon bonds in naphthalene are not of the same length. The bonds C1–C2, C3–C4, C5–C6 and C7–C8 are about 1.36 Å (136 pm) in length, whereas all the other carbon-carbon bonds are about 1.42 Å (142 pm) in length. This has been verified by x-ray diffraction and can be expected from the resonance structures, where the bonds C1–C2, C3–C4, C5–C6 and C7–C8 are double in two of the three structures, whereas all the others are double in only one.



Like benzene,naphthalene can undergo electrophilic aromatic substitution. For many electrophilic aromatic substitution reactions, naphthalene is more reactive than benzene, and reacts under milder conditions than does benzene. For example, while both benzene and naphthalene react with chlorine in the presenece of a ferric chloride or aluminium chloride catalyst, naphthalene and chlorine can react to form 1-chloronaphthalene even without a catalyst. Similarly, while both benzene and naphthalene can be alkylated using Friedel-Crafts reactions, naphthalene can also be alkylated by reaction with alkenes or alcohols, with sulfuric or phosphoric acid as the catalyst.

Mono-substitution of naphthalene has two possible isomeric products, corresponding to substitution at an alpha or beta position, respectively. Usually, the major product has the electrophile in the alpha position. The selectivity for alpha over beta substitution can be rationalized in terms of the resonance structures of the intermediate: for the alpha substitution intermediate, seven resonance structures can be drawn, of which four preserve an aromatic ring. For beta substitution, the intermediate has only six resonance structures, and only two of these are aromatic. Sulfonation, however, gives a mixture of the "alpha" product 1-naphthalenesulfonic acid and the "beta" product 2-naphthalenesulfonic acid, with the ratio dependent on reaction conditions.

Naphthalene can be hydrogenated under high pressure or with a suitable catalyst to give 1,2,3,4-tetrahydronaphthalene, a solvent sold under the trade name Tetralin. Further hydrogenation yields decahydronaphthalene or Decalin (C10H18, also known as bicyclo[4.4.0]decane). Oxidation of naphthalene with chromate or permanganate, or catalytic oxidation with O2 and a vanadium catalyst, gives phthalic acid.

Production

Most naphthalene is derived from coal tar. From the 1960s until the 1990s, significant amounts of naphthalene were also produced from heavy petroleum fractions during petroleum refining, but today petroleum-derived naphthalene represents only a minor component of naphthalene production.

Naphthalene is the most abundant single component of coal tar. While the composition of coal tar varies with the coal from which it is produced, typical coal tar is about 10% naphthalene by weight. In industrial practice, distillation of coal tar yields an oil containing about 50% naphthalene, along with a variety of other aromatic compounds. This oil, after being washed with aqueous sodium hydroxide to remove acidic components, chiefly various phenols, and with sulfuric acid to remove basic components, is fractionally distilled to isolate naphthalene. The crude naphthalene resulting from this process is about 95% naphthalene by weight. The chief impurity is the sulfur-containing aromatic compound thionaphthene. Petroleum-derived naphthalene is usually purer than that derived from coal tar. Where purer naphthalene is required, crude naphthalene can be further purified by recrystallizing it from any of a variety of solvents.

Incidence in nature

Trace amounts of naphthalene are produced by magnolias and specific types of deer. Naphthalene has also been found in the Formosan subterranean termite, possibly as a repellant against "ants, poisonous fungi and nematode worms."

Uses

Naphthalene's most familiar use is as a household fumigant, such as in mothballs. In a sealed container containing naphthalene pellets, naphthalene vapors build up to levels toxic to both the adult and larval forms of many moths that are destructive to textiles. Other fumigant uses of naphthalene include use in soil as a fumigant pesticide, and in attic spaces to repel animals.

In the past, naphthalene was administered orally to kill parasitic worms in livestock.

Larger volumes of naphthalene are used as a chemical intermediate to produce other chemicals. The single largest use of naphthalene is the industrial production of phthalic anhydride, although more phthalic anhydride is made from o-xylene than from naphthalene. Other naphthalene-derived chemicals include alkyl naphthalene sulfonate surfactants, and the insecticide carbaryl. Naphthalenes substituted with combinations of strongly electron-donating functional groups, such as alcohols and amines, and strongly electron-withdrawing groups, especially sulfonic acids, are intermediates in the preparation of many synthetic dyes. The hydrogenated naphthalenes tetrahydronaphthalene (Tetralin) and decahydronaphthalene (Decalin) are used as low-volatility solvents.

Health effects

In humans, exposure to large amounts of naphthalene may damage or destroy red blood cells. This could cause the body to have too few red blood cells until it replaces the destroyed cells. Humans, particularly children, have developed this condition after ingesting mothballs or deodorant blocks containing naphthalene. Some of the symptoms of this condition are fatigue, lack of appetite, restlessness, and pale skin. Exposure to large amounts of naphthalene may also cause nausea, vomiting, diarrhea, blood in the urine, and jaundice (yellow coloration of the skin).

When the U.S. National Toxicology Program exposed male and female rats and mice to naphthalene vapors on weekdays for two years (1), male and female rats exhibited: evidence of carcinogenic activity, based on increased incidences of adenoma and neuroblastoma of the nose, female mice exhibited some evidence of carcinogenic activity, based on increased incidences of alveolar and bronchiolar adenomas of the lung, and male mice exhibited no evidence of carcinogenic activity.

The International Agency for Research on cancer (IARC) (2) classifies naphthalene as possibly carcinogenic to humans [Group 2B]. It also points out that acute exposure causes cataracts in humans, rats, rabbits, and mice and, that haemolytic anaemia, described above, can occur in children and infants after oral or inhalation exposure or after maternal exposure during pregnancy.

Over 400 million people have an inherited condition called glucose-6-phosphate dehydrogenase deficiency. For these people, exposure to naphthalene is harmful and may cause hemolytic anemia, which causes their erythrocytes to break down.

Natron

Natron is a non-radioactive compound composed of the basic elements sodium, hydrogen, carbon, and oxygen. Some sources say that a simple mixture can be made with sodium bicarbonate, which is commonly known as baking soda, and sodium chloride, which is salt. Its color can vary from white, gray, yellow or it can even be colorless. The molecular weight is 286.14 gm. Natron's empirical formula is

Na***2***(CO***3***)x10(H***2***O) and its chemical formula is Na2CO3x10(H2O). Natron can be found in saline lake beds in arid environments. The name natron is Latin in origin meaning “Soda.” The density can range from 1.42- 1.47.

Uses for Natron

One common use was in ancient Egypt as a part of mummification. The mineral works as a drying agent, drawing the water out of the body. At the same time the bicarbonate, when subjected to moisture, increases the pH and creates a hostile environment for bacteria. Natron was also thought to promote spiritual safety for both the living and the dead. It was also added to castor oil to produce a smokeless fuel which allowed Egyptian artisans to paint

elaborate artworks inside ancient tombs without them becoming besmirched with soot. Natron has also been known to be used as a cleansing product for the home as well as the body which includes the teeth and was used as an early mouthwash. It has also been linked to early antiseptics if placed on wounds and minor cuts. It was also used to rid a house of vermin. Natron is also an ingredient in the making of the distinct color "Egyptian blue." Natron was used to make ceramics and glass as well as to solder precious metals together. If natron was mixed with salt, it could be used to preserve fish and meat. It could also be mixed with oil and it became an early form of soap. Natron was commonly used in glass-making, by the Romans and others, until trade declined after 640 AD.

Natron is used to make Bavarian pretzels. The dough is dipped into a natron solution to give it its brown color and distinctive flavor when baked.

Locations

Natron can be found in the following locations: Quebec, Canada (Rouville Co. and Mont Saint-Hilaire)

Wadi Natrum, Egypt

Showa Province, Ethiopia

Bács-Kiskun Co., Hungary (Great Hungarian Plain)

Szabolcs-Szatmár-Bereg Co., Hungary (Great Hungarian Plain)

Campania, Italy (Naples Province and Somma-Vesuvius Complex)

Northern Region of Russia (Murmanskaja Oblast', Kola Peninsula, Khibiny Massif, Lovozero Massif, Alluaiv Mt, Umbozero Mine, and Kedykverpakhk Mt)

England, UK (Cornwall, St Just District, Botallack - Pendeen Area, Botallack, and Botallack Mine)

California, USA (Inyo Co.)

Nevada, USA (Churchill Co., Soda Lake District, Humboldt Co., and Mineral Co.)

Oregon, USA (Lake Co.)

Washington, USA (Okanogan Co.)

Related compounds Benzenethiol

Phenol, also known under an older name of *carbolic acid*, is a colourless crystalline solid with a typical sweet tarry odor. Its chemical formula is C6H5OH and its structure is that of a hydroxyl group (-OH) bonded to a phenyl ring; it is thus an aromatic compound.

Phenols

The word phenol is also used to refer to any compound which contains a six-membered aromatic ring, bonded directly to a hydroxyl group (-OH). In effect, phenols are a class of organic compounds of which the phenol discussed in this article is the simplest member.

Properties

Phenol has a limited solubility in water (8.3 g/100 ml). It is slightly acidic: the phenol molecule has weak tendencies to lose the H+ ion from the hydroxyl group, resulting in the highly water-soluble phenoxide anion C6H5O. Compared to aliphatic alcohols, phenol shows much higher acidity,it even reacts with NaOH to lose H+ which aliphatic alcohols do not. This

is due to orbital overlap between the oxygen's lone pairs and the aromatic system, which delocalizes the negative charge throughout the ring and stabilizes the anion. This effect is attenuated, however, due to oxygen's relatively high electronegativity. [1]

Production

Phenol can be made from the partial oxidation of benzene or benzoic acid, by the cumene process, or by the Raschig process. It can also be found as a product of coal oxidation.

Uses

Phenol has antiseptic properties, and was used by Sir Joseph Lister in his pioneering technique of antiseptic surgery, though the skin irritation caused by continual exposure to phenol eventually led to the substitution of aseptic (germ-free) techniques in surgery. It is one of the main components of the commercial antiseptic TCP (trichlorophenol).

Phenol has anesthetic properties, and is the active ingredient in some oral anesthetics such as Chloraseptic spray.

It is also used in the production of drugs (it is the starting material in the industrial production of aspirin), weedkiller, and synthetic resins (Bakelite, one of the first synthetic resins to be manufactured, is a polymer of phenol with formaldehyde). Exposure of the skin to concentrated phenol solutions causes chemical burns which may be severe; in laboratories where it is used, it is usually recommended that polyethylene glycol solution is kept available for washing off splashes. Washing with large amounts of plain water (most labs have a safety shower or eye-wash) and removal of contaminated clothing are required, and immediate ER treatment for large splashes; particularly if the phenol is mixed with chloroform (a commonly used mixture in molecular biology for DNA purification). Notwithstanding the effects of concentrated solutions, it is also used in cosmetic surgery as an exfoliant, to remove layers of dead skin. It is also used in phenolization, a surgical procedure used to treat an ingrown nail, in which it is applied to the toe to prevent regrowth of nails.

Injections of phenol have occasionally been used as a means of rapid execution.

Phenol was also used as a means of extermination by the Nazis during the Second World War. Phenol injections were given to thousands of people in concentration camps, especially at Auschwitz-Birkenau. Injections were administered either by medical doctors or by their assistants; such injections were originally given intravenously, more commonly in the arm, but injection directly into the heart, so as to induce nearly instant death, was later preferred. [2]

Phenols are extremely harmful to cats. [3]

Salicylic acid

Chemical name 2-Hydroxybenzoic acid

Chemical formula $C_7H_6O_3$

Molecular mass 138.12 g/mol

Melting point 159 °C

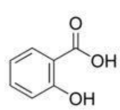
Boiling point 211 °C (2666 Pa)

Density 1.44 g/cm^3 (at 20 °C)

pKa 2.97

CAS number [69-72-7]

SMILES c1(O)ccccc1C(O)=O



Disclaimer and references

Salicylic acid is the chemical compound with the formula $C_6H_4(OH)CO_2H$, where the OH group is adjacent to the carboxylic acid group. This colorless crystalline organic acid is widely used in organic synthesis and functions as a plant hormone. It is probably best known as a compound that is chemically similar but not identical to the active component of aspirin. The name derives from the latin word for the willow tree (Salix), from whose bark it can be obtained.

Medicinal and cosmetic uses

Also known as beta hydroxy acid (compare to AHA), salicylic acid is the key additive in many skin-care products for the treatment of acne, psoriasis, callouses, corns, keratosis pilaris and warts. It treats acne by causing skin cells to slough off more readily, preventing

pores from clogging up. This effect on skin cells also makes salicylic acid an active ingredient in several shampoos meant to treat dandruff. Use of straight salicylic solution may cause hyperpigmentation on unpretreated skin for those with darker skin types (Fitzpatrick phototypes IV, V, VI), as well as with the lack of use of a broad spectrum sunblock.[1][2]

The medicinal properties of salicylate (mainly for fever relief) have been known since ancient times. The substance occurs in the bark of willow trees; the name salicylic acid is derived from salix, the Latin name for the willow tree. [3]

Aspirin (acetylsalicylic acid or ASA) can be prepared by the esterification of the phenolic hydroxyl group of salicylic acid.

Subsalicylate in combination with bismuth form the popular stomach relief aid known commonly as Pepto-Bismol. When combined, the two key ingredients help control diarrhea, nausea, heartburn, and gas. It is also a very mild anti-biotic.

Toxicological effects of 100% salicylic acid, however, are mostly harmful. It is harmful by ingestion, inhalation, and through skin absorption. It acts as an irritant, and chronic effects have shown 100% salicylic acid to cause DNA damage, and also cause allergic reactions after repeated exposure. This is why most acne treatment medications use a percent range of 2-5 in solution.

Other uses

- Salicylic acid is toxic if ingested in large quantities, but in small quantities is used as a food preservative and antiseptic in toothpaste. For some people with salicylate sensitivity even these small doses can be harmful.

Silver nitrate is a chemical compound with chemical formula $AgNO_3$. This nitrate of silver is a light-sensitive ingredient in photographic film and is a poisonous, corrosive compound. Silver nitrate crystals can be produced by dissolving silver in nitric acid and evaporating the solution. The compound notably stains skin a greyish or black color that is made visible after exposure to sunlight.

When making photographic film, silver nitrate is reacted with halide salts of sodium or potassium to form insoluble silver halide in situ in photographic gelatin, which is then applied to strips of tri-acetate or polyester. Photons from sunlight, X-rays or other sources, initiate a chemical chain reaction: when photons strike silver nitrate molecules, they free electrons from the halide ions. These free electrons roam through the crystal and settle in structural imperfections called sensitivity specks. These specks attract positive silver ions, which are then neutralized to form groups of stable silver atoms, creating a latent image that is chemically developed to reveal a photographic image.

Silver nitrate has antiseptic properties. It is sometimes dropped into newborn babies' eyes at birth to prevent contraction of gonorrhoea or chlamydia from the mother. Disposal of even small quantities of silver nitrate in toilets connected to a septic tank is guaranteed to destroy the septic bacteria and necessitate pumping out and flushing and seeding with fresh bacteria.

Fused silver nitrate, shaped into sticks, was traditionally called *lunar caustic*. It is used as a cauterizing agent.

In histology, silver nitrate is used for silver staining, for demonstrating proteins and nucleic acids. For this reason it is also used to demonstrate proteins in PAGE gels. It is also used as a stain in scanning electron microscopy.

Silver nitrate is used to prepare some silver-based explosives, such as the fulminate, azide, or acetylide, through a precipitation reaction.

Silver nitrate may be used to electroplate metals if dissolved in water.

Related salts Sodium acetate

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Sodium chloride, also known as *common salt*, *table salt*, or halite, is a chemical compound with the formula NaCl. Sodium chloride is the salt most responsible for the salinity of the ocean and of the extracellular fluid of many multicellular organisms. As the main ingredient in edible salt, it is commonly used as a condiment and food preservative.

Crystal structure

Sodium chloride forms crystals with cubic symmetry. In these, the larger chloride ions, shown to the left as green spheres, are arranged in a cubic close-packing, while the smaller sodium ions, shown to the left as blue spheres, fill the octahedral gaps between them.

Each ion is surrounded by six of the other kind. This same basic structure is found in many other minerals, and is known as the halite structure. This arrangement is known as cubic close packed (ccp).

It is held together with an ionic bond and electrostatic forces.

Biological importance

Sodium chloride is essential to life on Earth. Most biological tissues and body fluids contain a varying amount of salt.

Salt throughout history

Salt's preservative ability was a foundation of civilization. It eliminated dependency on the seasonal availability of food and allowed travel over long distances. By the Middle Ages, caravans consisting of as many as forty thousand camels traversed four hundred miles of the Sahara bearing salt, sometimes trading it for slaves.

During his protests in India, Gandhi performed the famous salt march to challenge the British-imposed monopoly on salt.

In religion

There are thirty-five references (verses) to salt in the Bible (King James Version), the most familiar probably being the story of Lot's wife, who was turned into a pillar of salt when she disobeyed the angels and looked back at the wicked city of Sodom (Genesis 19:26). In the Sermon on the Mount, Jesus also referred to his followers as the salt of the earth, a reference to salt's great value in the ancient world. Most of the time when talking about salt, the Bible is speaking of wisdom or age and wisdom combined.

In the native Japanese religion shinto, salt is seen as "corrupt" and can be used to purify (bless) locations and people, such as in Sumo Wrestling.

Production and use

Nowadays, salt is produced by evaporation of seawater or brine from other sources, such as brine wells and salt lakes, and by mining *rock salt*, called halite.

While most people are familiar with the many uses of salt in cooking, they might be unaware that salt is used in a plethora of applications, from manufacturing pulp and paper to setting dyes in textiles and fabric, to producing soaps and detergents. In most of Canada and the northern USA, large quantities of rock salt are used to help clear highways of ice during winter, although "Road Salt" loses its melting ability at temperatures below -15°C to -20°C (5°F to -4°F).

Synthetic Uses

Salt is also the raw material used to produce chlorine which itself is required for the production of many modern materials including PVC and pesticides.

Industrially, elemental chlorine is usually produced by the electrolysis of sodium chloride dissolved in water. Along with chlorine, this chloralkali process yields hydrogen gas and sodium hydroxide, according to the chemical equation

2 NaCl + 2 H2O ’ Cl2 + H2 + 2 NaOH

Sodium metal is produced commercially through the electrolysis of liquid sodium chloride. This is done in a Down's cell in which the NaCl is mixed with calcium chloride to lower the melting point below 700 °C. As calcium is more electropositive than sodium, no calcium will be formed at the cathode. This method is less expensive than the previous method of electrolyzing sodium hydroxide.

Flavour enhancer

Main article: Edible salt

Salt is commonly used as a flavour enhancer for food and has been identified as one of the basic tastes. Unfortunately, given its history, this has resulted in large sections of the developed world ingesting salt massively in excess of the required intake, particularly in colder climates where the required intake is much lower. This causes elevated levels of blood

pressure (hypertension) in some, which in turn is associated with increased risks of heart attack and stroke. Consuming salt in excess can also dehydrate the human body.

Biological uses

Many microorganisms cannot live in an overly salty environment: water is drawn out of their cells by osmosis. For this reason salt is used to preserve some foods, such as smoked bacon or fish. It has also been used to disinfect wounds. In medieval times salt would be rubbed into household surfaces as a cleansing agent.

De-icing

While salt was a scarce commodity in history, industrialized production has now made salt plentiful. About 51% of world output is now used by cold countries to de-ice roads in winter, see Grit bin. This works because salt and water form a eutectic mixture that has about a 10°C lower freezing point than pure water (see Freezing-point depression): the ions prevent regular ice crystals from forming (below 10°C salt will not prevent water from freezing). Concerns are arising that this use may be harmful to the environment though, and, in Canada, norms were developed to minimize the use of salt in de-icing.

Additives

The salt sold for consumption today is not pure sodium chloride. In 1911 Magnesium carbonate was first added to salt to make it flow more freely. In 1924 trace amounts of iodine in form of sodium iodide, potassium iodide or potassium iodate were first added, creating iodized salt to reduce the incidence of simple goiter.

Other facts

- Salty soil is generally unfit for agriculture, hence the practice of salting the earth.
- Due to its high concentration of salt, the Dead Sea has such a high density that some objects which are not normally buoyant can float on its surface. Humans float easily, having a density slightly less than that of pure water. (Only 8% of the salt in the Dead Sea is sodium chloride; 53% is magnesium chloride, 37% is potassium chloride.)
- The cities of Cincinnati, Detroit and Hutchinson, Kansas are on top of active salt mines.
- The Third Reich stored vast amounts of money, paintings and artworks in salt mines, and many important documents and items continue to be stored in former salt mines to this day. Salt mines are also used to store nuclear waste.

Sodium hypochlorite is a chemical compound with the formula NaClO. A solution of sodium hypochlorite is frequently used as a disinfectant and as a bleaching agent; indeed, often it is simply called "bleach", though other chemicals are sometimes given that name as well.

Production

Sodium hypochlorite may be prepared by absorbing chlorine gas in cold sodium hydroxide solution:

$2NaOH + Cl_2 \rightarrow NaCl + NaClO + H_2O$

Sodium hydroxide and chlorine are commercially produced by the chloralkali process, and there is no need to isolate them to prepare sodium hypochlorite. Hence NaClO is prepared industrially by the electrolysis of sodium chloride solution without any separation between the anode and the cathode. The solution must be kept below 40 °C (by cooling coils) to prevent the formation of sodium chlorate.

The commercial solutions always contain significant amounts of sodium chloride (common salt) as the main byproduct, as seen in the equation above.

Packaging and sale

Household bleach sold for use in laundering clothes is a 3-6% solution of sodium hypochlorite at the time of manufacture. Strength varies from one formulation to another and gradually decreases with long storage.

A 12% solution is widely used in waterworks for the chlorination of water. High-test hypochlorite (HTH) is sold for chlorination of swimming pools and contains approximately 30% sodium hypochlorite. The crystalline salt is also sold for the same use; this salt usually contains less than 50% of sodium hypochlorite. However, the level of "active chlorine" may be much higher.

Uses

In household bleach form, sodium hypochlorite is used for removal of stains from laundry. It is particularly effective on cotton fiber, which stains easily but bleaches well. 50 to 250 ml per load is usually recommended for a standard-size washer. Hot water increases

the activity of the bleach, owing to the thermal decomposition of hypochlorite which ultimately generates environmentally-undesirable chlorate.

A weak solution of 1% household bleach in warm water is used to sanitize smooth surfaces prior to brewing of beer or wine. Surfaces must be rinsed to avoid imparting flavors to the brew; these chlorinated byproducts of sanitizing surfaces are also harmful.

A 1 in 5 dilution of household bleach with water (1 part bleach to 4 parts water) is effective against many bacteria and some viruses, and is often the disinfectant of choice in cleaning surfaces in hospitals (Primarily in the United States). The solution is corrosive, and needs to be thoroughly removed afterwards, so the bleach disinfection is sometimes followed by an ethanol disinfection.

For shock chlorination of wells or water systems, a 2% solution of household bleach is used. For larger systems, HTH is more practical because lower rates can be used. The alkalinity of the sodium hypochlorite solution also causes the precipitation of minerals such as calcium carbonate, so that the shock chlorination is often accompanied by a clogging effect. The precipitate also preserves bacteria, making this practice somewhat less effective.

Sodium hypochlorite has been used for the disinfection of drinking water, at a concentration equivalent to about 1 liter of household bleach per 4000 liters of water is used. The exact amount required depends on the water chemistry, temperature, contact time, and presence or absence of sediment. In large-scale applications, residual chlorine is measured to titrate the proper dosing rate. For emergency disinfection, the US EPA recommends the use of 2 drops of 5%ac household bleach per quart of water. If the treated water doesn't smell of bleach, 2 more drops are to be added.

The use of chlorine-based disinfectants in domestic water, although widespread, has led to some controversy due to the formation of small quantities of harmful byproducts such as chloroform.

It is also used in dentistry, during root canal treatment, disinfecting the canal and dissolving any remaining pulp tissue. Historically, Henry Drysdale Dakin's solution (0.5%) had been used. Nowadays, 2.5-5.25% solutions are being used.

An alkaline solution (pH 11.0) of sodium hypochlorite is used to treat dilute (< 1 g/L) cyanide wastewater, e.g. rinsewater from an electroplating shop. In batch treatment operations, sodium hypochlorite has been used to treat more concentrated cyanide wastes, such as silver cyanide plating solutions. A well-mixed solution is fully treated when an excess of chlorine is detected.

Mechanism of action

Like all hypochlorites, sodium hypochlorite is a salt of hypochlorous acid, HClO. Sodium hypochlorite solution is a light yellow green transparent liquid. In water, it partially splits into the sodium cation Na+ and the hypochlorite anion ClO, while a substantial portion hydrolyses into sodium hydroxide and hypochlorous acid. The oxidizing power of the latter and of the hypochlorite anion cause the bleaching effect. The hypochlorite anion's negative charge, however, prevents it from diffusing through the cell walls of bacteria and microbes, making it a poor disinfectant. However, the hypochlorous acid molecules that exist in equilibrium with the hypochlorite anion, due to their neutral charge and small size, easily diffuse through the cell walls of bacteria. This changes the oxidation-reduction potential

(ORP) of the cell, and inactivates the enzyme triosephosphate dehydrogenase. Triosephosphate dehydrogenase (or glyceraldehyde 3-phosphate dehydrogenase/GAPDH) is essential for the digestion of glucose, but is particularly sensitive to oxidizing agents. Its inactivation effectively destroys the micro-organism's ability to function.

Cautions

Sodium hypochlorite is a strong oxidizer. Products of the oxidation reactions are corrosive. Solutions burn skin and cause eye damage, particularly when used in concentrated forms. However, as recognized by the NFPA, only solutions containing more than 40% sodium hypochlorite by weight are considered hazardous oxidizers. Solutions less than 40% are classified as a moderate oxidizing hazard (NFPA 430, 2000).

Household bleach and pool chlorinator solutions are typically stabilized by a significant concentration of lye (caustic soda, NaOH) as part of the manufacturing reaction. Skin contact will produce caustic irritation or burns due to defatting and saponification of skin oils and destruction of tissue. The slippery feel of bleach on skin is due to this process.

Sodium thiosulfate (hypo) is an effective chlorine neutralizer. Rinsing with a 5mg/L solution, followed by washing with soap and water, quickly removes chlorine odor from the hands.

Chlorination of drinking water can oxidize organic contaminants, producing trihalomethanes (also called haloforms), which are carcinogenic. The extent of the hazard thus created is a subject of disagreement.

Mixing bleach with some household cleaners can be hazardous. For example, mixing an acid cleaner with sodium hypochlorite bleach generates chlorine gas. Mixing with ammonia solutions produces chloramines. Both chlorine gas and chloramine gas are toxic. Bleach can react violently with hydrogen peroxide and produce oxygen gas:

$H_2O_2 + NaClO$ ’ $NaCl + H_2O + O_2$

It is estimated that there are about 3300 accidents needing hospital treatment caused by sodium hypochlorite solutions each year in British homes (RoSPA, 2002).

Antivirals

Antiviral drugs are a class of medication used specifically for treating viral infections. Like antibiotics, specific antivirals are used for specific viruses. Antiviral drugs are one class of antimicrobials, a larger group which also includes antibiotics, anti-fungal and anti-parasitic drugs. They are relatively harmless to the host, and therefore can be used to treat infections. They should be distinguished from viricides, which actively deactivate virus particles outside the body.

Most of the antivirals now available are designed to help deal with HIV, herpesvirus, which is best known for causing cold sores but actually covers a wide range of diseases, and the hepatitis B and C viruses, which can cause liver cancer. Researchers are now working to extend the range of antivirals to other families of pathogens.

The emergence of antivirals is the product of a greatly expanded knowledge of the genetic and molecular function of organisms, allowing biomedical researchers to understand the structure and function of viruses, major advances in the techniques for finding new drugs, and the intense pressure placed on the medical profession to deal with the human immunodeficiency virus (HIV), the cause of the deadly acquired immunodeficiency syndrome (AIDS) epidemic. Though no one could sensibly claim that AIDS has been a benefit to humankind, it has certainly done much to advance the state of antiviral technology.

History

Modern medical science and practice has something of an armory of effective tools, ranging from antiseptics and anesthetics to vaccines and antibiotics. One field in which medicine has been traditionally weak, however, is in finding drugs to deal with viral infections. To be sure, highly effective vaccines have been developed to prevent such diseases, but traditionally, once somebody came down sick with a virus, there was little that could be done but recommend rest and plenty of fluids until the disease ran its course.

The first experimental antivirals were developed in the 1960s, mostly to deal with herpesviruses, and were found using traditional trial-and-error drug discovery methods.

Since the mid-1980s, that scenario has changed dramatically. Dozens of antiviral treatments are now available, and most medical researchers feel we are only scratching at the surface of what can be done with these new drugs.

Development of antiviral drugs

Viruses, not quite proper living things, consist of a genome and sometimes a few enzymes (biocatalysts) stored in a capsule made of protein, and very rarely covered with a lipid (fat) layer. Viruses cannot reproduce on their own, and so they propagate by hijacking cells to do the job for them.

To develop early antivirals, researchers grew cultures of cells and infected them with the target virus. They then introduced chemicals into the cultures thought likely to inhibit viral activity, and observed whether the level of virus in the cultures rose or fell. Chemicals that seemed to have an effect were selected for closer study.

This was a very time-consuming, hit-or-miss procedure, and in the absence of a good knowledge of how the target virus worked, not very good at discovering antivirals that were effective and had few side effects. It wasn't until the 1980s, when the full genetic sequences of viruses began to be unraveled, that researchers began to learn how viruses worked in detail, and exactly what kinds of molecules were needed to jam their machinery.

The general idea behind modern antiviral drug design is to identify viral proteins, or parts of proteins, that can be disabled. These "targets" should generally be as unlike any proteins or parts of proteins in humans as possible, to reduce the likelihood of side effects. The targets should also be common across many strains of a virus, or even among different

species of virus in the same family, so a single drug will have broad effectiveness. For example, a researcher might target a critical enzyme synthesized by the virus, but not the patient, that is common across strains, and see what can be done to interfere with its operation.

Once targets are identified, candidate drugs can be selected, either from drugs already known to have appropriate effects, or by actually designing the candidate at the molecular level with a computer-aided design program.

In either case, the candidates can be synthesized by plugging the gene that synthesizes that protein into bacteria or other kinds of cells. The bacteria or cells are then cultured for mass production of the protein, which can then be sifted by "rapid screening" technologies to see which of the candidates are the most effective.

Antiviral drug design strategies

Researchers working on such "rational drug design" strategies for developing antivirals have tried to attack viruses at every stage of their life cycles. Viral life cycles vary in their precise details depending on the species of virus, but they all share a general pattern:

- Attachment to a host cell.
- Release of viral genes and possibly enzymes into the host cell.
- Replication of viral components using host-cell machinery.
- Assembly of viral components into complete viral particles.
- Release of viral particles to infect new host cells.

The best time to attack a virus is as early as possible in its life cycle. In a sense, this is exactly what vaccines do. Vaccines traditionally consist of a weakened or killed version of a pathogen, though more recently "subunit" vaccines have been devised that consist strictly of protein targets from the pathogen. They stimulate the immune system without doing serious harm to the host, and so when the real pathogen attacks the subject, the immune system responds to it quickly and blocks it.

Vaccines have an excellent track record for effectiveness, but they are of limited use in treating a patient who has already been infected. That's where antiviral drugs come in.

One approach is to interfere with the ability of a virus to get into a target cell. The virus has to take a sequence of actions to do this, beginning with binding to a specific "receptor" molecule on the surface of the host cell and ending with the virus "uncoating" inside the cell and releasing its payload. Viruses that have a lipid envelope must also fuse their envelope with the target cell, or with a vesicle that transports them into the cell, before they can uncoat.

This stage of viral replication can be inhibited in two ways: 1. Using agents which mimic the virus-associated protein (VAP) and bind to the cellular receptors. This may include VAP Anti-idiotypic antibodies, anti-receptor antibodies, and natural ligands of the receptor and anti-receptor antibodies. 2. Using agents which mimic the receptor and bind to the VAP. This includes anti-VAP antibodies, receptor anti-idiotypic antibodies, extraneous receptor and synthetic receptor mimics.

This strategy of designing drug can be very expensive. The process of generating anti-idiotypic antibodies is not fully understood. And it has very poor pharmacokinetics.

A very early stage of viral infection is viral entry, when the virus attaches to and enters the host cell. A number of "entry-inhibiting" or "entry-blocking" drugs are being developed to fight HIV. HIV most heavily targets the immune-system white blood cells known as "helper T cells", and identifies these target cells through T-cell surface receptors designated "CD4" and "CCR5". Attempts to interfere with the binding of HIV with the CD4 receptor have failed to stop HIV from infecting helper T cells, but research continues on trying to interfere with the binding of HIV to the CCR5 receptor in hopes that will be more effective.

However, two entry-blockers, amantadine and rimantadine, have been introduced to combat influenza, and researchers are working on entry-inhibiting drugs to combat hepatitis B and C virus.

One entry-blocker is pleconaril. Pleconaril works against rhinoviruses, which cause the common cold, by blocking a pocket on the surface of the virus that controls the uncoating process. This pocket is similar in most strains of rhinoviruses and enteroviruses, which can cause diarrhea, meningitis, conjunctivitis, and encephalitis.

A second approach is to target the processes that synthesize virus components after a virus invades a cell. One way of doing this is to develop "nucleotide or nucleoside analogues" that look like the building blocks of RNA or DNA, but jam the enzymes that synthesize the RNA or DNA once the analogue is incorporated.

The first successful antiviral, aciclovir, is a nucleoside analogue, and is effective against herpesvirus infections. The first antiviral drug to be approved for treating HIV, zidovudine (AZT), is also a nucleoside analogue.

An improved knowledge of the action of reverse transcriptase has led to better nucleoside analogues to treat HIV infections. One of these drugs, lamivudine, has been approved to treat hepatitis B, which uses reverse transcriptase as part of its replication process. Researchers have gone farther and developed inhibitors that do not look like nucleosides, but can still block reverse transcriptase.

Other targets being considered for HIV antivirals include RNase H, which is a component of reverse transcriptase that splits the synthesized DNA from the original viral RNA; and integrase, which splices the synthesized DNA into the host cell genome.

Once a virus genome becomes operational in a host cell, it then generates messenger RNA (mRNA) molecules that direct the synthesis of viral proteins. Production of mRNA is initiated by proteins known as transcription factors. Several antivirals are now being designed to block attachment of transcription factors to viral DNA.

Genomics has not only helped find targets for many antivirals, it has provided the basis for an entirely new type of drug, based on "antisense" molecules. These are segments of DNA or RNA that are designed as "mirror images" to critical sections of viral genomes, and the binding of these antisense segments to these target sections blocks the operation of those genomes. A phosphorothioate antisense drug named fomivirsen has been introduced, used to treat opportunistic eye infections in AIDS patients caused by cytomegalovirus, and other antisense antivirals are in the works. An antisense structual type that has proven especially valuable in research is Morpholino antisense. Morpholino oligos have been used to experimentally suppress many viral types including caliciviruses, flaviviruses (including WNV , Dengue and HCV), and coronaviruses and are currently in clinical development.

Yet another devious antiviral technique inspired by genomics is a set of drugs based on ribozymes, which are enzymes that will cut apart viral RNA or DNA at selected sites. In the

natural order of things, ribozymes are used as part of the viral manufacturing sequence, but these synthetic ribozymes are designed to cut RNA and DNA at sites that will disable them.

A ribozyme antiviral to deal with hepatitis C is in field testing, and ribozyme antivirals are being developed to deal with HIV. An interesting variation of this idea is the use of genetically modified cells that can produce custom-tailored ribozymes. This is part of a broader effort to create genetically modified cells that can be injected into a host to attack pathogens by generating specialized proteins that block viral replication at various phases of the viral life cycle.

Some viruses include an enzyme known as a protease that cuts apart viral protein chains so they can be assembled into their final configuration. HIV includes a protease, and so considerable research has been performed to find "protease inhibitors" to attack HIV at that phase of its life-cycle. Protease inhibitors became available in the 1990s and have proven effective, though they can have odd side-effects, for example causing fat to build up in unusual places. Improved protease inhibitors are now in development.

The final stage in the life cycle of a virus is the release of completed viruses from the host cell, and this step has also been targeted by antiviral drug developers. Two drugs named zanamivir and oseltamivir that have been recently introduced to treat influenza prevent the release of viral particles by blocking a molecule named neuraminidase that is found on the surface of flu viruses, and also seems to be constant across a wide range of flu strains.

A second category of tactics for fighting viruses involves encouraging the body's immune system to attack them, rather than attacking them directly. Some antivirals of this sort do not focus on a specific pathogen, instead stimulating the immune system to attack a range of pathogens.

One of the best-known of this class of drugs are interferons, which inhibit viral synthesis in infected cells. One form of human interferon named "interferon alpha" is well-established as a treatment for hepatitis B and C, and other interferons are also being investigated as treatments for various diseases.

A more specific approach is to synthesize antibodies, protein molecules that can bind to a pathogen and mark it for attack by other elements of the immune system. Once researchers identify a particular target on the pathogen, they can synthesize quantities of identical "monoclonal" antibodies to link up that target. A monoclonal drug is now being sold to help fight respiratory syncytial virus in babies, and another is being tested as a treatment for hepatitis B.

Examination of the genomes of viruses and comparison with the human genome show that some are devious, generating proteins that mimic those used by the human immune system, confusing the immune-system response. Researchers are now hunting for antivirals that can recognize these intruder proteins and disable them.

All drugs designed to fight pathogens have a common problem: over the long run, the pathogens evolve to acquire resistance to the drugs. This means that no antiviral will ever be a permanent solution. In fact, the structure of an antiviral compound will have to be tweaked as its target pathogen changes.

This is the nature of the game. However, antivirals are now promising to be the biggest innovation in pharmaceuticals since the introduction of antibiotics during the Second World War, and promise to be a major step forward in health care.

Antiretroviral drugs

Antiretroviral drugs are medications for the treatment of infection by retroviruses, primarily HIV. Different classes of antiretroviral drugs act at different stages of the HIV life cycle. Combination of several (typically three or four) antiretroviral drugs is known as *Highly Active Anti-Retroviral Therapy* (*HAART*).

Organizations such as the National Institutes of Health (Bethesda, Maryland, USA) recommend offering antiretroviral treatment to all patients with HIV-related symptoms. However, because of the complexity of selecting and following a regimen, the severity of the side effects, and the importance of compliance to prevent viral resistance, such organizations emphasize the importance of involving patients in therapy choices and recommend analyzing the risks and the potential benefits to patients without symptoms.[1]

Classes of antiretroviral drugs

Antiretroviral drugs are broadly classified by the phase of the retrovirus life-cyle that the drug inhibits. There are thus five broad classifications of antiretroviral drugs in development, though only the first three classes currently have licensed examples:

- Reverse transcriptase inhibitors (RTIs) target construction of viral DNA by inhibiting activity of reverse transcriptase. There are two subtypes of RTIs with different mechanisms of action: nucleoside-analogue RTIs are incorporated into the viral RNA leading to chain termination, while non-nucleoside-analogue RTIs distort the binding potential of the reverse transcriptase enzyme.
- Protease inhibitors (PIs) target viral assembly by inhibiting the activity of protease, an enzyme used by HIV to cleave nascent proteins for final assembly of new virons.
- Fusion inhibitors block HIV from fusing with a cell's membrane to enter and infect it.
- Integrase inhibitors inhibit the enzyme integrase, which is responsible for integration of viral DNA into the DNA of the infected cell. There are several integrase inhibitors currently under clinical trial but none are commercially available.
- Entry inhibitors block HIV-1 from the host cell by binding CCR5, a molecule on the viral membrane termed a co-receptor that HIV-1 normally uses for entry into the cell.

Fixed dose combinations

Fixed dose combinations are multiple antiretroviral drugs combined into a single pill.

Synergistic enhancers

Synergistic enhancers usually do not possess any antiretroviral properties alone, but when they are taken concurrently with antiretroviral drugs they enhance the effect of that drug.

Combination therapy

The life cycle of HIV can be as short as about 1.5 days: from viral entry into a cell; through replication, assembly, and release of additional viruses; to infection of other cells. HIV lacks proofreading enzymes to correct errors made when it converts its RNA into DNA via reverse transcription. Its short life cycle and high error rate cause the virus to mutate very rapidly, resulting in a high genetic variability of HIV. Most of the mutations either are inferior to the parent virus (often lacking the ability to reproduce at all) or convey no advantage, but some of them have a natural selection superiority to their parent and can enable them to slip past defenses such as the human immune system and antiretroviral drugs. The more active copies of the virus, the greater the possibility that one resistant to antiretroviral drugs will be made, so antiretroviral combination therapy defends against resistance by suppressing HIV replication as much as possible.

Combinations of antiretrovirals create multiple obstacles to HIV replication to keep the number of offspring low and reduce the possibility of a superior mutation. If a mutation arises that conveys resistance to one of the drugs being taken, the other drugs continue to suppress reproduction of that mutation. With rare exceptions, no individual antiretroviral drug has been demonstrated to suppress an HIV infection for long; these agents must be taken in combinations in order to have a lasting effect. As a result the standard of care is to use combinations of antiretroviral drugs. Combinations usually comprise two nucleoside-analogue RTIs and one non-nucleoside-analogue RTI or protease inhibitor.[2]

Combinations of antiretrovirals are subject to positive and negative synergies, which limits the number of useful combinations. For example, ddI and AZT inhibit each other, so taking them together is less effective than taking either one separately. Other issues further limit some people's treatment options from antiretroviral drug combinations, including their complicated dosing schedules and often severe side effects.

In recent years drug companies have worked together to combine these complex regimens into simpler formulas, termed fixed dose combinations. For instance, two pills containing two or three medications each can be taken twice daily. This greatly increases the ease with which they can be taken, which in turn increases adherence, and thus their effectiveness over long term. Lack of adherence is a primary cause of resistence development in medication-experienced patients. The highly mutanegenic nature of HIV demands 98% adherence to drug cocktails for the drugs to be totally effective (that means missing less than 6 doses per year). Patients able to adhere at this rate and higher can maintain one regimen

for up to a decade without developing resistence. This greatly increases chances of long-term survival, as it leaves more drugs available to the patient for longer periods of time.

Current treatment guidelines

Antiretroviral drug treatment guidelines have changed many times. Early recommendations attempted a "hit hard, hit early" approach. A more conservative approach followed, with a starting point somewhere between 350 and 500 CD4+ T cells/mm^3. The current guidelines use new criteria to consider starting HAART, as described below. However, there remain a range of views on this subject and the decision of whether to commence treatment ultimately rests with the patient and their doctor.

The current guidelines for antiretroviral therapy (ART) from the World Health Organization reflect the 2003 changes to the guidelines and recommend that in resource-limited settings (that is, developing nations), HIV-infected adults and adolescents should start ART when HIV infection has been confirmed and one of the following conditions is present [3]):

- Clinically advanced HIV disease;
- WHO Stage IV HIV disease, irrespective of the CD4 cell count;
- WHO Stage III disease with consideration of using CD4 cell counts less than 350/µl to assist decision making;
- WHO Stage I or II HIV disease with CD4 cell counts less than 200/µl.

The treatment guidelines in the USA are set by the United States Department of Health and Human Services (DHHS). The current guidelines for adults and adolescents were stated on October 6, 2005 [4]:

- All patients with history of an AIDS-defining illness or severe symptoms of HIV infection regardless of CD4+ T cell count receive ART.
- Antiretroviral therapy is also recommended for asymptomatic patients with less than 200 CD4+ T cells/µl.
- Asymptomatic patients with CD4+ T cell counts of 201–350 cells/µl should be offered treatment.
- For asymptomatic patients with CD4+ T cell of greater than 350 cells/µl and plasma HIV RNA greater than 100,000 copies/ml, most experienced clinicians defer therapy but some clinicians may consider initiating treatment.
- Therapy should be deferred for patients with CD4+ T cell counts of greater than 350 cells/µl and plasma HIV RNA less than 100,000 copies/mL.

The preferred initial regimens are[5]:

- efavirenz + zidovudine + lamivudine

efavirenz + tenofovir + emtricitabine
lopinavir boosted with ritonavir + zidovudine + lamivudine
lopinavir boosted with ritonavir + tenofovir + emtricitabine.

In countries with a high rate of baseline resistance, resistance testing is recommended prior to starting treatment; or, if the initiation of treatment is urgent, then a "best guess" treatment regimen should be started which is then modified on the basis of resistance testing. In the UK, there is 11.8% medium to high level resistance at baseline to the

combination of zidovudine + lamivudine + efavirenz, and 6.4% medium to high level resistance to stavudine + lamivudine + nevirapine.[6]

Because HIV disease progression in children is more rapid than in adults, and laboratory parameters are less predictive of risk for disease progression, particularly for young infants, treatment recommendations from the DHHS have been more aggressive in children than in adults, the current guidelines were published November 3, 2005 [7].

In 2005, the Centers for Disease Control and Prevention in the United States recommended a 28-day HIV drug regimen for those who have been exposed to HIV (HIV Postexposure Prophylaxis [PEP])[8]. The drugs have demonstrated effectiveness in preventing the virus nearly 100% of the time in those who received treatment within the initial 24 hours of exposure. The effectiveness falls to 52% of the time in those who are treated within 72 hours; those not treated within the first 72 hours are not recommended candidates for the regimen.

Concerns

There are several concerns about antiretroviral regimens. The drugs can have serious side effects.[9] Regimens can be complicated, requiring patients to take several pills at various times during the day, although treatment regimens have been greatly simplified in recent years. If patients miss doses, drug resistance can develop.[10] Also, anti-retroviral drugs are costly, and the majority of the world's infected individuals do not have access to medications and treatments for HIV and AIDS.

Research to improve current treatments includes decreasing side effects of current drugs, further simplifying drug regimens to improve adherence, and determining the best sequence of regimens to manage drug resistance.

Responses to Treatment in Older Adults

As people age, their bodies aren't able to repair and rebuild damaged cells, organs or tissues as rapidly as those of younger people. Diseases like HIV that attack and destroy the body's defenses can exacerbate this slowing and increase the risk of developing additional medical problems like diabetes and high blood pressure, and more physical limitations than younger adults with HIV. In the early years of the HIV epidemic (before HAART), older adults' health deteriorated more rapidly than that of younger individuals - regardless of CD4 count. Several studies found that older adults had lower CD4 counts at diagnosis, faster progression to an AIDS diagnosis, more opportunistic infections, and a shorter survival rate than younger adults, regardless of when they were first diagnosed with HIV.

Recent studies have found that a person's age doesn't interfere with the ability of HAART to reduce viral load, but there may be differences between younger and older people in how well the immune system responds to treatment. A study published in AIDS (2000) by Roberto Manfredi and Francesco Chiodo examined the effect of HAART on older people (defined as 55 or older) compared to younger people (35 or younger). The study included 21 older people (8 women, 13 men) and 84 younger people (29 women, 55 men). The researchers found that both groups responded to HAART, especially in reducing viral load. However, CD4 counts did not increase as much in the older people relative to the younger

ones. On average, CD4 counts increased from 212 to 289 for older adults after one year of HAART. During the same period, CD4 counts rose from 231 to 345 for younger people.

Some people may have a very low CD4 count even though they have an undetectable viral load. This may be related to decreased activity in the thymus (the gland where CD4 cells are made). A 2001 study in AIDS conducted by researchers in Los Angeles included 80 HIV-positive veterans (13 were over 55 and 67 were younger). Although both groups of veterans showed dramatic reductions in viral load once they were on treatment, the researchers found significant differences in CD4 levels at 3, 9, 15, and 18 months. After one year on HAART, average CD4 counts increased by 50 for the older men, compared to increases of 100 for the younger ones. This difference was not related to baseline HIV viral load, coinfection with hepatitis C, or the race/ethnicity of participants. These studies represent an important first step in understanding how their age may affect older adults' response to HIV treatment, but more studies are needed to understand the long-term effects of age on HAART in older adults.

Limitations of antiretroviral drug therapy

If an HIV infection becomes resistant to standard HAART, there are limited options. One option is to take larger combinations of antiretroviral drugs, an approach known as *mega-HAART* or salvage therapy. Salvage therapy often increases the drugs' side-effects and treatment costs. Another is to take only one or two antiretroviral drugs, specifically ones that induce HIV mutations that diminish the virulence of the infection. The most common resistance mutation to lamivudine (3TC) in particular appears to do this. Thus, 3TC can be somewhat effective even alone and when the virus is resistant to it.

If an HIV infection becomes sufficiently resistant to antiretroviral-drugs, treatment becomes more complicated and prognosis may deteriorate. Treatment options continue to improve as additional new drugs enter clinical trials. However, the limited distribution of many such drugs denies their benefits to patients in the developing world.

Drug holidays (or "structured treatment interruptions"), are intentional discontinuations of antiretroviral drug treatment. Studies of such interruptions attempt to increase the sensitivity of HIV to antiretroviral drugs. The interruptions attempt to change the selection pressure from the drug resistance back toward resistance to the human immune system, thus breeding a more drug-susceptible virus. HIV spends some of its life-cycle in a state where its DNA is entirely integrated into human DNA. Under certain conditions, drug-resistant strains of the virus can remain dormant in this state, since CD4 T-cells also are dormant when not aroused by invading organisms. The resistant strain can then reemerge when antiretroviral drugs are re-introduced.

Intermittent therapy is an experimental approach designed to reduce exposure to antiretroviral drugs in an effort to mitigate side-effects. Intermittent therapy differs from treatment interruptions in that it involves using a much shorter cycle of switching on and off the antiviral drugs. Studies of such approaches include schedules of Week-on, week-off (also known as "wowo") and Five-days-on, two-days-off (also known as "foto"), which skips treatment on weekends. They also seek to determine what kinds of patients are best suited for this approach. However, initial data suggest that intermittent therapy is ineffective and results in drug resistance.

It is still unclear whether suppressing or even eliminating HIV will be adequate to restore normal immune function in the long term, since HIV can damage the ability of the thymus to produce normally diverse T-cells. Also, rapid suppression of HIV and partial restoration of the immune system sometimes produces a dangerous hypersensitivity reaction, immune reconstitution inflammatory syndrome. Research continues in these areas.

Adverse effects

Adverse effects of antiretroviral drugs vary by drug, by ethnicity, and by individual, and by interaction with other drugs, including alcohol. Hypersensitivity to some drugs may also occur in some individuals. The following list is not complete, but includes several of the common adverse effects experienced by patients taking some antiretroviral drugs: [11]

- Abdominal pain

Alopecia
Anemia
Asthenia
Diarrhea
Dizziness (Vertigo)
Fanconi syndrome
Flatulence
Headache
Hepatitis
Hyperbilirubinemia
Hypercholesterolemia (Dyslipidemia, Hyperlipidemia, high cholesterol)
Hyperpigmentation (of nails, palms, or soles)
Ingrown nails
Insomnia
Jaundice
Liver failure
Malaise
Mental confusion
Myalgia
Myalgic Encephalomyelitis (chronic fatigue syndrome)
Myopathy
Nausea
Neutropenia
Nightmares
Oral ulcers
Pancreatitis
Paresthesia (numbness)
Peripheral neuropathy
Rash
Renal failure or insufficiency
Somnolence (drowsiness)
Stevens-Johnson syndrome

Change in taste perception
Vomiting
Xeroderma (dry skin)
Xerostomia (dry mouth)

Protease inhibitor

Protease inhibitors (PIs) are a class of medication used to treat or prevent infection by viruses, including HIV and Hepatitis C. PIs prevent viral replication by inhibiting the activity of protease, an enzyme used by the viruses to cleave nascent proteins for final assembly of new virons.

Protease inhibitors have been developed or are presently undergoing testing for treating various viruses:

- HIV/AIDS: antiretroviral protease inhibitors (saquinavir, ritonavir, indinavir, nelfinavir etc.)

Hepatitis C: experimental agents: BILN 2061, VX 950.

Given the specificity of the target of these drugs there is the risk, as in antibiotics, of the development of drug-resistant mutated viruses. To reduce this risk it is common to use together different drugs aimed at different targets.

Antiretrovirals

Protease inhibitors were the second class of antiretroviral drugs developed. In all cases, patents remain in force until 2010 or beyond.

Saquinavir Saquinavir has trade names Fortovase® (soft gel capsule) and Invirase® (hard gel capsule).

Ritonavir Ritonavir has the trade name: Norvir®.

Indinavir Indinavir has the trade name: Crixivan®.

Nelfinavir Nelfinavir has the trade name Viracept®.

Amprenavir Amprenavir has the trade name Agenerase®. The FDA approved it April 15, 1999, making it the sixteenth FDA-approved antiretroviral. It was the first protease inhibitor approved for twice-a-day dosing instead of needing to be taken every eight hours. The convenient dosing came at a price, as the dose required is 1,200mg, delivered in eight very large gel capsules. Production of Agenerase® was discontinued by the manufacturer December 31, 2004, as it has been superseded by fosamprenavir.

Lopinavir Lopinavir is only marketed as a combination. See Kaletra® below.

Atazanavir Atazanavir has the trade name Reyataz®.

Fosamprenavir Fosamprenavir, with the trade name Lexiva®, is a pro-drug of amprenavir. The FDA approved it October 20, 2003. The human body metabolizes fosamprenavir in order to form amprenavir, which is the active ingredient. That metabolization increases the duration that amprenavir is available, making fosamprenavir a slow-release version of amprenavir and thus reduces the amount of pills required versus standard amprenavir.

Tipranavir Tipranavir, also known as tipranavir disodium, has the trade name Aptivus®.

Neuraminidase inhibitors

Neuraminidase inhibitors are a class of antiviral drugs whose mode of action relies on blocking the function of viral neuraminidase protein, thus preventing the virus from budding from the host cell.

Oseltamivir, Zanamivir and Peramivir belong to this class.

Unlike the M2 inhibitors, which work only against the influenza A, neuraminidase inhibitors act against both influenza A and B.

Routes oral

Oseltamivir (INN) (IPA: [Rs[lÈtæmjvir]) is an antiviral drug that is used in the treatment and prophylaxis of both Influenzavirus A and Influenzavirus B. Like zanamivir, oseltamivir is a neuraminidase inhibitor. It acts as a transition-state analogue inhibitor of influenza neuraminidase, preventing new viruses from emerging from infected cells.

Oseltamivir was the first orally active neuraminidase inhibitor commercially developed. It is a prodrug, which is hydrolysed hepatically to the active metabolite, the free carboxylate of oseltamivir (GS4071). It was developed by Gilead Sciences and is currently marketed by Hoffmann-La Roche (Roche) under the trade name *Tamiflu*. It is generally available by prescription only.

With increasing fears about the potential for a new influenza pandemic, oseltamivir has received substantial media attention. Production capacity is limited, and governments (and even some private individuals) are stockpiling the drug.

Clinical use

Indications and dosage

Oseltamivir is indicated for the treatment of infections due to influenza A and B virus in people at least one year of age, and prevention of influenza in people at least 1 year or older. The usual adult dosage for treatment of influenza is 75 mg twice daily for 5 days, beginning within 2 days of the appearance of symptoms and with decreased doses for children and

patients with renal impairment. Oseltamivir may be given as a preventive measure either during a community outbreak or following close contact with an infected individual. Standard prophylactic dosage is 75 mg once daily for patients aged 13 and older, which has been shown to be safe and effective for up to six weeks. (Roche, 2005; Rossi, 2006)

Use in avian influenza

It has also been found that the standard recommended dose incompletely suppresses viral replication in at least some patients with H5N1 influenza, rendering therapy ineffective and increasing the risk of viral resistance (de Jong et al. 2005). Accordingly, it has been suggested that higher doses and longer durations of therapy should be used for treatment of patients with the H5N1 virus (de Jong et al. 2005, Ward et al. 2005). See Resistance section, below.

Chokephaibulkit et al recommend the use of oseltamivir in pediatric patients, based on experience with one patient.

After following WHO protocols in treating 41 victims of the H5N1 bird flu virus (19% of the world-wide cases of bird flu reported to date), Nguyen Tuong Van, MD, who runs the intensive care unit of the Center for Tropical Diseases in Hanoi, Vietnam concluded that Tamiflu, the drug most widely stockpiled around the world to combat a potential bird flu pandemic, is "useless." According to this article, the WHO confirmed Van's experience stating that Tamiflu has not been "widely successful in human patients", but speculated the drug has not been administered until late in the disease in many Asian countries.

Co-administration with probenecid

It has been suggested that co-administration of oseltamivir with probenecid could extend the limited supply of oseltamivir. Probenecid reduces renal excretion of the active metabolite of oseltamivir. One study showed that 500 mg of probenicid given every six hours doubled both the peak plasma concentration (Cmax) and the half-life of oseltamivir, increasing overall systemic exposure (AUC) by 2.5-fold. (Hill et al., 2002) Although the evidence for this interaction comes from a study by Roche, it was publicised only in October 2005 by a doctor who had reviewed the data (Butler, 2005). Probenecid was used in similar fashion during World War II to extend limited supplies of penicillin, and is still currently used to increase penicillin concentrations in serious infections.

Dosage forms

Oseltamivir is marketed by Roche under the trade name Tamiflu, as capsules (containing oseltamivir phosphate 98.5 mg equivalent to oseltamivir 75 mg) and as a powder for oral suspension (oseltamivir phosphate equivalent to oseltamivir 12 mg/mL).

Adverse effects

Common adverse drug reactions (ADRs) associated with oseltamivir therapy include: nausea, vomiting, diarrhea, abdominal pain, and headache. Rare ADRs include: hepatitis and elevated liver enzymes, rash, allergic reactions including anaphylaxis, and Stevens-Johnson syndrome. (Rossi, 2006)

Various other ADRs have been reported in postmarketing surveillance including: toxic epidermal necrolysis, cardiac arrhythmia, seizure, confusion, aggravation of diabetes, and haemorrhagic colitis.

Neurological effects

In May 2004, the safety division of Japan's health ministry ordered changes to the literature accompanying oseltamivir to add neurological and psychological disorders as possible adverse effects, including: impaired consciousness, abnormal behavior, and hallucinations. Various cases of psychological disorders were associated with oseltamivir therapy between 2000–2004, including several deaths.

On 2005-11-18 the United States Food and Drug Administration (FDA) issued a report regarding the paediatric safety of oseltamivir, which stated that there was insufficient evidence to claim a causal link between oseltamivir use and the deaths of 12 Japanese children (only two from neurological problems). However, it was recommended that a warning was added to the Product Information regarding rashes associated with oseltamivir therapy (Pediatric Advisory Committee, 2005).

In November 2006, reports of bizarre behavior in Japanese children, including three deaths from falls, resulted in the FDA amending the warning label to include possible side effects of delirium, hallucinations, or other related behavior.[1]

Mode of action

Oseltamivir is a neuraminidase inhibitor. By blocking the activity of the neuraminidase, Oseltamivir prevents new viral particles from being released by infected cells.

Resistance

As with other antivirals, resistance to the agent was expected with widespread use of oseltamivir, though the emergence of resistant viruses was expected to be less frequent than with amantadine or rimantadine. The resistance rate reported during clinical trials up to July 2004 was 0.33% in adults, 4.0% in children, and 1.26% overall. Mutations conferring resistance are single amino acid residue substitutions in the neuraminidase enzyme (Ward et al., 2005).

Mutant H3N2 influenza A virus isolates resistant to oseltamivir were found in 18% of a group of 50 Japanese children treated with oseltamivir (Kiso et al., 2004). This rate was similar to another study where resistant isolates of H1N1 influenza virus were found in 16.3% of another cohort of Japanese children (Ward et al., 2005). Several explanations were proposed by the authors of the studies for the higher-than-expected resistance rate detected. First, children typically have a longer infection period, giving a longer time for resistance to

develop. Second, Kiso et al. (2004) claim to have used more rigorous detection techniques than previous studies. Third, the dosage regimen in Japan is different from that of other nations, and some children may have been given a suboptimal dosage of oseltamivir.

High-level resistance has been detected in one girl suffering from H5N1 avian influenza in Vietnam. She was being treated with oseltamivir at time of detection (Le et al., 2005; World Health Organization, 2005).

de Jong et al. (2005) describe resistance development in two more Vietnamese patients suffering from H5N1, and compare their cases with six others. They suggest that the emergence of a resistant strain may be associated with a patient's clinical deterioration. They also note that the recommended dosage of oseltamivir does not always completely suppress viral replication, a situation that could favor the emergence of resistant strains. Moscona (2005) gives a good overview of the resistance issue, and says that personal stockpiles of Tamiflu could lead to under-dosage and thus the emergence of resistant strains of H5N1.

Resistance is of concern in the scenario of an influenza pandemic (Wong and Yuen 2005), and may be more likely to develop in avian influenza than seasonal influenza due to the potentially longer duration of infection by novel viruses. Kiso et al. (2004) suggest that "a higher prevalence of resistant viruses should be expected" during a pandemic.

The genetic sequence for the neuraminidase enzyme is highly conserved across virus strains. This means that there are relatively few variations, and there is also evidence that variations that do occur tend to be less "fit." Thus, mutations that convey resistance to oseltamivir may also tend to cripple the virus by giving it an otherwise less-functional enzyme. The lack of variation in neuraminidase gives two advantages to oseltamivir and zanamivir, the drugs that target that enzyme. First, these drugs work on a broader spectrum of influenza strains. Second, the development of a robust, resistant virus strain appears to be less likely (Ward et al., 2005). It is worth noting that the oseltamivir-resistant strains detected by Kiso et al. (2004) all appeared within individual children after treatment with oseltamivir – the children did not catch the resistant strains in human-to-human or bird-to-human transmission.

Pandemic fears

Oseltamivir was widely used during the H5N1 avian influenza epidemic in Southeast Asia in 2005. In response to the epidemic, various governments – including those of the United Kingdom, Canada, United States and Australia – stockpiled quantities of oseltamivir in preparation for a possible pandemic. Though large, the quantities stockpiled would not have been sufficient to protect the entire population of these countries.

In October 2005, the Indian drug company Cipla announced their plan to begin manufacture of generic oseltamivir without license from Roche. Most patent laws allow governments to authorise supply from generic companies, subject to remuneration to patent owners to address public health problems, including emergencies, although Roche has announced its intention to remain the sole supplier of the drug. Cipla argues that it can legally sell oseltamivir to India and 49 other developing countries, possibly as early as January 2006. Also in October, it was announced that Roche was in discussions with four generic drug manufacturers about the possibility of issuing sublicenses to increase production.

In late October 2005, Roche announced that it was suspending shipments to pharmacies in the United States and Canada until the North American seasonal flu outbreak began, to address concerns about private stockpiling and to preserve supplies for seasonal influenza. It said that, when distribution resumes in Canada, the remaining available drug will be saved for use in high-risk settings like long-term care facilities and hospitals. ales were suspended in Hong Kong as well, and on November 8, also in China. Roche said it would instead send all supplies to China's health ministry.

On November 9, 2005, Vietnam became the first country to be granted permission by Roche to produce a generic version of oseltamivir. The week before, Thai authorities said they would begin producing generic oseltamivir, claiming that Roche had not patented Tamiflu in Thailand. The first Thai generic oseltamivir was produced in February 2006 and are to be available to the public in July 2006.

In December 2005, Roche also signed a sublicense for complete oseltamivir production with China's Shanghai Pharmaceuticals, and by March 2006 a sublicense had also been granted to India's Hetero. In June 2006, the Chinese government gave Shanghai Pharmaceuticals permission to proceed, based upon tests of the domestic production. The company said it planned to market the drug by the end of the month.

In late May 2006, the World Health Organization asked Roche to be ready to ship an emergency stockpile of oseltamivir to Indonesia if needed. The alert was in response to suspected human-to-human transmission within a family and was planned to last for two weeks

U.S. Government policy and oseltamivir

In November, 2005, U.S. president George W. Bush requested that Congress fund $7.1 billion in emergency spending for flu pandemic preparedness (the Senate had already passed an $8.1 billion bill). Bush's plan included $1.4 billion for government purchases of antiviral drugs.

Some commentators question the motives of the U.S. government's endorsement and planned purchase of oseltamivir, noting Secretary of Defense Donald Rumsfeld's close ties to Gilead Sciences, rightsholder to the oseltamivir patent. Rumsfeld is a former chairman of Gilead, and federal disclosure forms indicate that he owns between USD$5 million and USD$25 million in Gilead stock (Schwartz 2005). The rise in Gilead's share prices from USD$35 to USD$57 per share will have added between USD$2.5 million to USD$15.5 million to Rumsfeld's net worth.

On the other hand, at least one Democratic Senator has criticized Bush for not planning to buy enough antiviral drugs

Personal stockpiling of oseltamivir

The short supply of oseltamivir has prompted some individuals to stockpile the drug. Several American states, including Massachusetts and Colorado, have issued advisories strongly discouraging this practice.

One argument against individual stockpiling is that limited drugs should be kept for more strategic or ethical deployment, that is, to hard-hit areas, to people in critical roles (e.g., healthcare and government workers), to people vulnerable to seasonal flu, or to people who actually have come down with avian influenza. Ethical arguments are sometimes made: Why should affluent people (or nations) have preferred access to antiviral medications? Illegal importation may divert the drug from poorer countries where the risk of avian influenza is actually higher.

In the New England Journal of Medicine, Moscona (2005) argues that the use of personal stockpiles of oseltamivir could result in the administration of low dosages, allowing for the development of drug-resistant virus strains. Many stockpilers will only have ten 75 mg pills (the current recommended dosage for oseltamivir), but this may be insufficient for the treatment of H5N1. (de Jong et al., 2005)

Another argument is that it would be difficult for home users to determine whether illegally-imported Tamiflu is counterfeit. This is genuinely a potential problem, but, in the face of a shortage, some individuals may be willing to face such a risk. In December 2005, 53 packages of counterfeit Tamiflu tablets were intercepted by the US Customs Service in South San Francisco. The packages were labeled "Generic Tamiflu". Roche officials know of only one instance of counterfeit Tamiflu appearing outside of the United States: incorrectly-labelled tablets found in Holland, which contained only Vitamin C and lactose. However, sophisticated criminals could produce convincing fake packaging in the future

A fourth purported problem is that the H5N1 virus can be reliably diagnosed only in a small number of labs around the world; therefore, there is no way for home users to know whether flu-like symptoms are the result of avian flu or a more benign ailment. This argument lacks face validity, since treatment must begin before such tests results would be available anyway.

Veterinary use

Oseltamivir appears to be active against canine parvovirus, feline panleukopenia, the canine respiratory complex known as "kennel cough," and the emerging disease dubbed "canine flu", an equine virus that began affecting dogs in 2005. Veterinary investigation of its use for canine parvo and canine flu is ongoing, but many shelters and rescue groups have reported great success employing oseltamivir in the early stages of these illnesses.

Chemical synthesis

Commercial syntheses

The current production method includes two reaction steps with potentially hazardous azides.

The synthesis commences from naturally available ()-shikimic acid. The 3,4-pentylidene acetal mesylate is prepared in three steps: esterification with ethanol and thionyl chloride; ketalization with para-toluenesulfonic acid and 3-pentanone; and mesylation with triethylamine and methanesulfonyl chloride. Reductive opening of the ketal under modified

Hunter conditions (JOC 1993, 58, 6756) in dichloromethane yields an inseparable mixture of isomeric mesylates. The corresponding epoxide is formed under basic conditions with potassium bicarbonate. Using the inexpensive Lewis acid magnesium bromide diethyl etherate (commonly prepared fresh by the addition of magnesium turnings to 1,2-dibromoethane in benzene:diethyl ether), the epoxide is opened with allyl amine to yield the corresponding 1,2-amino alcohol. The water-immiscible solvents methyl tert-butyl ether and acetonitrile are used to simplify the workup procedure, which involved stirring with 1 M aqueous ammonium sulfate. Reduction on palladium, promoted by ethanolamine, followed by acidic workup yielded the deprotected 1,2-aminoalcohol. The aminoalcohol was converted directly to the corresponding allyl-diamine in an interesting cascade sequence that commences with the unselective imination of benzaldehyde with azeotropic water removal in methyl tert-butyl ether. Mesylation, followed by removal of the solid byproduct triethylamine hydrochloride, results in an intermediate that was poised to undergo aziridination upon transimination with another equivalent of allylamine. With the librated methanesulfonic acid, the aziridine opens cleanly to yield a diamine that immediately undergoes a second transimination. Acidic hydrolysis then removed the imine. Selective acylation with acetic anhydride (under buffered conditions, the 5-amino group is protonated owing to a considerable difference in pKa, 4.2 vs 7.9, preventing acetylation) yields the desired N-acetylated product in crystalline form upon extractive workup. Finally, deallylation as above, yielded the freebase of oseltamivir, which was converted to the desired oseltamivir phosphate by treatment with phosphoric acid. The final product is obtained in high purity (99.7%) and an overall yield of 17-22% from ()-shikimic acid. It is noted that the synthesis avoids the use of potentially explosive azide reagents and intermediates; however, the synthesis actually used by Roche uses azides. Roche has other routes to oseltamivir that do not involve the use of ()-shikimic acid as a chiral pool starting material, such as a Diels-Alder route involving furan and ethyl acrylate or an isophthalic acid route, which involves catalytic hydrogenation and enzymatic desymmetrization.

2006 Corey synthesis

In 2006 the group of E.J. Corey published a novel route also bypassing shikimic acid starting from butadiene and acrylic acid. The inventors choose not to patent this procedure which is described below. Strictly speaking the synthesis is a formal total synthesis, as the final product to be characterized was the BOC-derivative.

Butadiene 1 reacts in an asymmetric Diels-Alder reaction with the esterfication product of acrylic acid and 2,2,2-Trifluoroethanol 2 catalysed by the CBS catalyst. The ester 3 is converted into an amide in 4 by reaction with ammonia and the next step to lactam 5 is an iodolactamization with iodine initiated by trimethylsilyltriflate. The amide group is fitted with a BOC protective group by reaction with Boc anhydride in 6 and the iodine substituent is removed in an elimination reaction with DBU to the alkene 7. Bromine is introduced in 8 by an allylic bromination with NBS and the amide group is cleaved with ethanol and caesium carbonate accompanied by elimination of bromide to the diene ethyl ester 9. The newly formed double bond is functionalized with N-bromoacetamide 10 catalyzed with Tin(IV) bromide with complete control of stereochemistry. In the next step the bromine atom in 11

is displaced by the nitrogen atom in the amide group with the strong base KHMDS to the aziridine 12 which in turn is opened by reaction with 3-pentanol 13 to the ether 14. In the final step the BOC group is removed with phosphoric acid and the oseltamivir phosphate *15* is formed.

Production shortage/shikimic acid

In early 2005, Roche announced a production shortage. (See Pandemic Fears, below). According to Roche, the major bottleneck in oseltamivir production is the availability of shikimic acid, which cannot be synthesised economically and is only effectively isolated from Chinese star anise, an ancient cooking spice. Although most autotrophic organisms produce shikimic acid, the isolation yield is low. A shortage of star anise is one of the key reasons why there is a worldwide shortage of Tamiflu (as at 2005). Star anise is grown in four provinces in China and harvested between March and May. It is also produced in Lang Son province, Vietnam. The shikimic acid is extracted from the seeds in a ten-stage manufacturing process. Thirteen grams of star anise make 1.3 grams of shikimic acid, which can be made into 10 oseltamivir 75 mg capsules. Ninety percent of the harvest is already used by Roche in making oseltamivir.

Some academic experts and other drug companies are disputing the difficulty of producing shikimic acid by means other than star anise extraction. An alternative method for production of the acid involves fermentation of genetically-modified bacteria. Other potential sources of shikimic acid include the ginkgo tree. In addition, quinic acid, derived from the bark of the cinchona tree of the Democratic Republic of the Congo, is a potential alternative base material for the production of oseltamivir.

However, as is clear by the multistep synthesis shown above, although the major bottleneck for Roche may be the availability of shikimic acid, production of oseltamivir is very involved. Increasing production volume (by Roche or others) would require construction of extensive new facilities (which may not be amenable to scaleup and, even if identical on paper, may not necessarily produce acceptable yields), and even if current facilities could handle a larger feedstock quantity, there would be a delay in production as the material makes it down the pipeline (~6 months or so).

In March 2006, Roche announced that it was making utilizing the resources of 15 external contractors in 9 countries, allowing production to expand to "as much as 400 million doses annually by the end of this year"

Canadian generic drug company Apotex is attempting to modify Oseletamivir to use a synthetic alternative to shikimic acid.

Routes Inhalation

Zanamivir (INN) (IPA: [zYÈnæmjvir]) is a neuraminidase inhibitor used in the treatment of and prophylaxis of both Influenzavirus A and Influenzavirus B. Zanamivir was the first neuraminidase inhibitor commercially developed. It is currently marketed by GlaxoSmithKline under the trade name *Relenza*.

Development

Zanamivir was developed in 1989 by scientists at the Australian biotechnology company Biota, working in conjunction with the CSIRO and the Victorian College of Pharmacy. The development was part of Biota's ongoing program to develop antiviral agents through rational drug design.

The strategy relied on the availability of the crystal structure of influenza neuraminidase which was achieved by x-ray crystallography. It was known as far back as 1974 that 2-deoxy-2,3-didehydro-N-acetylneuraminic acid (DANA), a sialic acid analogue, was an inhibitor of neuraminidase.[1] Using the crystal structure of neuraminidase and DANA as a starting point, the researchers employed a computer-aided process to attempt to design a molecule which was a better fit for (and therefore inhibited) the active site of neuraminidase. Zanamivir, a transition-state analogue inhibitor of neuraminidase, was the result.[2]

In 1990, zanamivir was licensed to Glaxo (now GlaxoSmithKline) for exclusive worldwide development and marketing. In 1999, the product was approved for marketing in the US and subsequently has been registered by GSK in a total of 70 countries.

Limitations

Whilst zanamivir proved to be a potent and effective inhibitor of influenza neuraminidase and inhibitor of influenza virus replication in vitro and in vivo, this didn't necessarily translate into a successful clinical treatment for influenza. In clinical trials it was found that zanamivir was able to reduce the time to symptom resolution by 1.5 days provided therapy was started within 48 hours of the onset of symptoms.

A further limitation concerns the poor oral bioavailability of zanamivir. This meant that oral dosing was impossible, limiting dosing to the parenteral routes. Zanamivir, therefore, is administered by inhalation - a route that was chosen for patient compliance with therapy. But even this route of administration is not acceptable to many in the community.

Commercial difficulties

Biota, being only a small company, was not able to bring the drug to market by itself. Consequently, it was licensed to Glaxo (now GlaxoSmithKline) to complete development and to market internationally as Relenza, delivered via Glaxo's proprietary, and some would say cumbersome, Diskhaler inhalation device. The license agreement entitled Biota to receive a 7% royalty on Glaxo's sales of Relenza.

A combination of factors has resulted in the limited commercial success of zanamivir (Relenza). The relatively small effect on the timecourse of influenza symptoms, the inhalation dosage form, a less-than-ideal device, and high expense make it a difficult product to market well. And although zanamivir was the first neuraminidase inhibitor to the market, it had only a few months lead over the second entrant, oseltamivir (Tamiflu), with an oral formulation much preferred by patients. Faced with this competition, GSK effectively abandoned the product.

When first marketed in 1999/00, Relenza captured close to 50% of the global market for neuraminidase inhibitors. But after the launch year, GSK cut virtually all promotion and other support for Relenza, allowing the product's sales and market share to slide in every major market over the following four years. By 2004 Relenza held only a 3% share of the estimated US$330 million global market.

In May 2004, Biota issued a writ against GSK for failing to support and promote Relenza. The writ claimed that GSK was in breach of several obligations:

- GSK restricted Relenza to its proprietary Diskhaler system, and did not adequately pursue alternative or improved inhalation systems.
- GSK withdrew support for crucial post-approval clinical studies designed to expand the product's use and market acceptance.
- After the launch year, GSK failed to properly launch Relenza in a number of countries where the product was registered, and allowed registrations to be stopped, cancelled or scheduled for cancellation.
- After the launch year, GSK withdrew promotion support for Relenza, allowing the sales and market share to decline in all key markets, even in those markets where there was no direct competition.

Developments from zanamivir

Zanamivir was the first of the neuraminidase inhibitors. Despite the limited commercial success of this drug, the work and strategies employed in the development of zanamivir were important first-steps in the development of further members of this class including oseltamivir and the candidate drug RWJ-270201 (Phase I trials). As a result more effective and potent treatments for influenza may be developed in the future.

Interferons (IFNs) are natural proteins produced by the cells of the immune system of most vertebrates in response to challenges by foreign agents such as viruses, bacteria, parasites and tumor cells. Interferons belong to the large class of glycoproteins known as cytokines.

The discovery of interferon

While aiming to develop an improved vaccine for smallpox, two Japanese virologists, Yasu-ichi Nagano and Yasuhiko Kojima working at the then Institute for Infection Disease at the University of Tokyo, noticed that rabbit-skin or testis previously inoculated with UV-inactivated virus exhibited inhibited viral growth when re-infected at the same site with live virus. They hypothesised that this was due to some “facteur inhibiteur” (inhibitory factor), and began to characterise it by fractionation of the UV-irradiated viral homogenates using an ultracentrifuge. They published these findings in 1954 in the French journal now known as “Journal de la Société de Biologie”.[1] While this paper demonstrated that the activity could be separated from the virus particles, it could not reconcile the antiviral activity demonstrated in the rabbit skin experiments, with the observation that the same supernatant led to the production of antiviral antibodies in mice. A further paper in 1958, involving triple-ultracentrifugation of the homogenate demonstrated that the inhibitory factor was distinct from the virus particles, leading to trace contamination being ascribed to the 1954 observations.[2][3]

Meanwhile, the Scottish virologist Alick Isaacs and the Swiss researcher Jean Lindenmann, at the National Institute for Medical Research in London, noticed an interference effect caused by heat-inactivated influenza virus on the growth of live influenza virus in fragments of chick chorioallantoic membrane. They published their results in 1957;[4] in this paper they coined the term ‘interferon’, and today that specific interfering agent is known as a ‘Type I interferon’.

Nagano’s work was never fully appreciated in the scientific community; possibly because it was printed in French, but also because his in vivo system was perhaps too complex to provide clear results in the characterisation and purification of interferon. As time passed, Nagano became aware that his work had not been widely recognised, yet did not actively seek reevaluation of his status in field of interferon research. As such, the majority of the credit for discovery of the interferon goes to Isaacs and Lindenmann, with whom there is no record of Nagano ever having made personal contact.[5]

Types of interferon

Three major classes of interferons have been described for humans, Type I, type II and type III, classified based on the type of receptor through which they signal.

Type I IFN

Human type I IFNs comprise a vast and growing group of IFN proteins, designated IFN-± (alpha), IFN-² (beta), IFN-º (kappa), IFN-´ (delta), IFN-µ (epsilon), IFN-Ä (tau), IFN-É (omega) and IFN-¶ (zeta, also known as limitin)[6].[7] The IFN-± proteins come in 13 subtypes that are called IFNA1, IFNA2, IFNA4, IFNA5, IFNA6, IFNA7, IFNA8, IFNA10, IFNA13, IFNA14, IFNA16, IFNA17, IFNA21. These genes for these IFN-± molecules are found together in a cluster on chromosome 9. Two types of IFN-² have been described, IFN-²1 and IFN-²3[8] (a gene designated IFN-²2 is actually IL-6). IFN-µ, –º, -Ä, and –¶ appear, at this time, to come in

a single isoform in humans. IFN-É, although having only one functional form described to date, has several pseudogenes.[9][10][11][12][13][14][15] Homologous molecules to type I IFNs are found in many species, including most mammals, and some have been identified in birds, reptiles, amphibians and fish species.[16] All type I IFNs bind to a specific cell surface receptor complex known as the IFN-± receptor (IFNAR) that consists of IFNAR1 and IFNAR2 chains.

Type II IFN

A sole member makes up the type II IFNs that is called IFN-³ (gamma). Mature IFN-³ is an anti-parallel homodimer, which binds to the IFN-³ receptor (IFNGR) complex to elicit a signal within its target cell. IFNGR is made up of two subunits each of molecules designated IFNGR1 and IFNGR2.

Type III IFN

The recently classified type III IFN group consists of three IFN-» (lamda) molecules called IFN-»1, IFN-»2 and IFN-»3 (also called IL29, IL28A and IL28B respectively).[17] These IFNs signal through a receptor complex consisting of IL10R2 (also called CRF2-4) and IFNLR1 (also called CRF2-12). [18]

The signaling pathway of interferons

While there is evidence to suggest other signaling mechanisms exist, the JAK-STAT signaling pathway is the best-characterised and commonly accepted IFN signaling pathway.

Sources and functions of inteferons

Interferons in general have several effects in common. They are antiviral and possess antioncogenic properties, macrophage and natural killer lymphocyte activation, and enhancement of major histocompatibility complex glycoprotein classes I and II, and thus presentation of foreign (microbial) peptides to T cells. In a majority of cases, the production of interferons is induced in response to microbes such as viruses and bacteria and their products (viral glycoproteins, viral RNA, bacterial endotoxin, bacterial flagella, CpG DNA), as well as mitogens and other cytokines, for example interleukin 1, interleukin 2, interleukin-12, tumor necrosis factor and colony-stimulating factor, that are synthesised in the response to the appearance of various antigens in the body. Their metabolism and excretion take place mainly in the liver and kidneys. They rarely pass the placenta and the blood-brain barrier.

Type I interferons

IFN-± and IFN-² are secreted by many cell types including lymphocytes (NK cells, B-cells and T-cells), macrophages, fibroblasts, endothelial cells, osteoblasts and others. They

stimulate both macrophages and NK cells to elicit and anti-viral response, and are also active against tumors. IFN-É is released by leukocytes at the site of viral infection or tumors.

Type II interferons

IFN-^{3} is involved in the regulation of the immune and inflammatory responses; in humans, there is only one type of interferon-gamma. It is produced in activated T-cells and natural killer cells. IFN-^{3} has some anti-viral and anti-tumor effects, but these are generally weak. However, this cytokine potentiates the effects of the type I IFNs. IFN-^{3} released by Th1 cells recruits leukocytes to a site of infection, resulting in increased inflammation. It also stimulates macrophages to kill bacteria that have been engulfed. IFN-^{3} released by Th1 cells is also important in regulating the Th2 response. As IFN-^{3} is vitally implicated in the regulation of immune response, its production can lead to autoimmune disorders.

Viral induction of interferons

All classes of interferon are very important in fighting RNA virus infections. However, their presence also accounts for some of the host symptoms, such as sore muscles and fever. They are secreted when abnormally large amounts of dsRNA are found in a cell. dsRNA is normally present in very low quantities. The dsRNA acts like a trigger for the production of interferon. The gene that codes for this cytokine is switched on in an infected cell, and the interferon synthesized and secreted to surrounding cells.

As the original cell dies from the cytolytic RNA virus, these thousands of viruses will infect nearby cells. However, these cells have received interferon, which essentially warns these other cells that there's a wolf in the pack of sheep. They then start producing large amounts of a protein known as protein kinase R (or PKR). If a virus chooses to infect a cell that has been “pre-warned” by interferon, it is like charging into a hail of bullets for the virus. The PKR is activated by the dsRNA, and begins transferring phosphate groups (phosphorylating) to a protein known as eIF2, a eukaryotic translation initiation factor. After phosphorylation, eIF2 has a reduced ability to initiate translation, the production of proteins coded by cellular mRNA. This prevents viral replication, but also inhibits normal cell ribosome function, killing both the virus and the host cell if the response is active for a sufficient amount of time. All RNA within the cell is also degraded, preventing the mRNA from being translated by eIF2 if some of the eIF2 failed to be phosphorylated.

Pharmaceutical uses

Interferon was scarce and expensive until 1980 when the interferon gene was inserted into bacteria using recombinant DNA technology, allowing mass cultivation and purification from bacterial cultures. Several different types of interferon are now approved for use in humans, and interferon therapy is used (in combination with chemotherapy and radiation) as a treatment for many cancers. When used in the systemic therapy, IFN-± and IFN-^{3} are mostly administered by an intramuscular injection. The injection of interferons in the muscle, in the vein, or under skin is generally well tolerated. The most frequent side-effects

are flu-like symptoms: increased body temperature, feeling ill, fatigue, headache, muscle pain, convulsion, dizziness, hair thinning, and depression. Erythema, pain and hardness on the spot of injection are also frequently observed. All known effects are usually reversible and disappear a few days after the therapy has been finished. However, there are some serious side effects and the patient is advised to read the accompanying pamphlet.

More than half of hepatitis C patients treated with interferon respond with better blood tests and better liver biopsies. There is some evidence that giving interferon immediately following infection can prevent hepatitis C; however, people infected by hepatitis C often do not display symptoms of HCV until months or years later.

More recently, the FDA approved pegylated interferon-alpha, in which polyethylene glycol is added to make the interferon last longer in the body. (Pegylated interferon-alpha-2b was approved in January 2001; pegylated interferon-alpha-2a was approved in October 2002.) The pegylated form is injected once weekly, rather than three times per week for conventional interferon-alpha. Used in combination with the antiviral drug ribavirin, pegylated interferon produces sustained cure rates of 75% or better in people with genotype 2 or 3 hepatitis C (which is easier to treat) but still less than 50% in people with genotype 1 (which is most common in the U.S. and Western Europe).

Interferon-beta (Interferon beta-1a and Interferon beta-1b) is used in the treatment and control of the neurological disorder multiple sclerosis. By an as-yet-unknown mechanism, interferon-beta inhibits the production of Th1 cytokines and the activation of monocytes.

Administered intranasally in very low doses, interferon is extensively used in Eastern Europe and Russia as a method to prevent and treat viral respiratory diseases such as cold and flu. It is claimed that the treatment can lower the risk of infection by as much as 60-70%. Mechanisms of such action of interferon are not well understood; it is thought that doses must be larger by several orders of magnitude to have any effect on the virus. Consequently, most Western scientists are sceptical of these claims.[19]

Disinfectants

Disinfectants are antimicrobial agents that are applied to non-living objects to destroy microorganisms, the process of which is known as *disinfection*. Disinfectants should generally be distinguished from antibiotics that destroy microorganisms within the body, and from antiseptics, which destroy microorganisms on living tissue. Sanitisers are high level

disinfectants that kill over 99.9% of a target microorganism in applicable situations. Not all disinfectants and sanitisers can sterilise (the complete elimination of all microorganisms), and those that can depend entirely on their mode of application. Bacterial endospores are most resistant to disinfectants, however some viruses and bacteria also posess some tolerance.

Properties

The ideal disinfectant would offer complete sterilisation, without harming other forms of life, be inexpensive, and non-corrosive. Unfortunately ideal disinfectants do not exist. All disinfectants are also, by their very nature, potentially harmful (even toxic) to humans or animals. They should be treated with appropriate care. Most come with safety instructions printed on the packaging, which should be read in full before using the disinfectant. Most modern household disinfectants contain Bitrex, an exceptionally bitter substance designed to discourage ingestion, as an added safety measure. Those that are used indoors should never be mixed with other cleaning products as chemical reactions can occur. They are frequently used in hospitals, dental surgeries, kitchens and bathrooms to kill infectious organisms.

The choice of the disinfectant to be used depends on the particular situation. Some disinfectants have a wide spectrum (kill nearly all microorganisms), whilst others kill a smaller range of disease-causing organisms but are preferred for other properties (they may be non-corrosive, non-toxic, or inexpensive).

The disinfecting properties of sunlight (ultra-violet) are powerful. Basic hygiene, rather than total reliance on chemicals, is important in the fight against bacteria, which generally prefer a warm-moist-dark environment. There are arguments for creating or maintaining conditions which are not conducive to bacterial survival and multiplication, rather than attempting to kill them with chemicals. Bacteria have a very rapid multiplication rate, which enables them to 'evolve' rapidly. Should some bacteria survive a chemical attack, they give rise to the next generation. Thus they are able to develop resistance to hostile chemicals. For this reason, some question the wisdom of impregnating cloths, cutting boards and worktops in the home with bactericidal chemicals. Hygiene in is important in prevention of foodborne illness.

Types of disinfectants

Alcohols

Alcohols, usually ethanol or isopropanol, are wiped over benches and skin and allowed to evaporate for quick disinfection. They have wide microbiocidal activity, are non corrosive, but can be a fire hazard. They also have limited residual activity due to evaporation, and have a limited activity in the presence of organic material. Alcohols are more effective combined with water, 70% alcohol is more active than 95% alcohol. Alcohol is not effective against fungal or bacterial spores.

Aldehydes

Aldehydes, such as Glutaraldehyde, have a wide microbiocidal activity and are sporocidal and fungicidal. They are partly inactivated by organic matter and have slight residual activity.

Halogens

- *Chloramine* is used in drinking water treatment instead of chlorine because it produces less disinfection byproducts.
- *Chlorine* is Used to disinfect swimming pools, and is added in small quantities to drinking water to reduce waterborne diseases.
- *Hypochlorites* (Sodium hypochlorite), often in the form of common household bleach, are used in the home to disinfect drains, and toilets. Other hypochlorites such as calcium hypochlorite are also used, especially as a swimming pool additive. Hypochlorite gives off free chlorine and it is the chlorine that is the true disinfectant. Hypobromite solutions are also sometimes used.
- Iodine is usually dissolved in an organic solvent or as Lugol's iodine solution. It is used in the poultry industry. It is added to the birds' drinking water. Although no longer recommended because it increases scar tissue formation and increases healing time, tincture of iodine has also been used as an antiseptic for skin cuts and scrapes.

Oxidising agents

Oxidising agents act by oxidising the cell membrane of microorganisms, which results in a loss of structure and leads to cell lysis and death.

- Chlorine dioxide is used as an advanced disinfectant for drinking water to reduce waterborne diseases. In certain parts of the world, it has largely replaced chlorine because it forms fewer byproducts. Sodium chlorite, sodium chlorate, and potassium chlorate are used as precursors for generating chlorine dioxide.
- Hydrogen peroxide is used in hospitals to disinfect surfaces. It is sometimes mixed with colloidal silver. It is often preferred because it causes far fewer allergic reactions than alternative disinfectants. Also used in the food packaging industry to disinfect foil containers. A 3% solution is also used as an antiseptic. When hydrogen peroxide comes into contact with the catalase enzyme in cells it is broken down into water and a hydroxyl free radical. It is the damage caused by the oxygen free radical that kills bacteria. However, as recent studies have show hydrogen peroxide to be toxic to growing cells as well as bacteria, its use as an antiseptic is no longer recommended.
- Ozone is a gas that can be added to water for sanitation.
- *Peracetic acid* is a disinfectant produced by reacting hydrogen peroxide with acetic acid. It is broadly effective against microorganisms and is not deactivated by catalase and peroxidase, the enzymes which break down

hydrogen peroxide. It also breaks down to food safe and environmentally friendly residues (acetic acid and hydrogen peroxide), and therefore can be used in non-rinse applications. It can be used over a wide temperature range (0-40°C), wide pH range (3.0-7.5), in clean-in-place (CIP) processes, in hard water conditions, and is not affected by protein residues.

- Potassium permanganate ($KMnO_4$) is a red crystalline powder that colours everything it touches, and is used to disinfect aquariums. It is also used widely in community swimming pools to disinfect ones feet before entering the pool. Typically, a large shallow basin of $KMnO_4$/water solution is kept near the pool ladder. Participants are required to step in the basin and then go into the pool. Additionally, it is widely used to disinfect community water ponds and wells in tropical countries, as well as to disinfect the mouth before pulling out teeth. It can be applied to wounds in dilute solution; potassium permanganate is a very useful disinfectant.

Phenolics

Phenolics are the active ingredient in most bottles of "household disinfectant". They are also found in some mouthwashes and in disinfectant soap and handwashes. Phenol is probably the oldest known disinfectant as it was first used by Lister, when it was called carbolic acid. It is rather corrosive to the skin and sometimes toxic to sensitive people, so the somewhat less corrosive phenolic o-phenylphenol is often used in favour. Hexachlorophene is a phenolic which was once used as a germicidal additive to some household products but was banned due to suspected harmful effects.

Quaternary ammonium compounds

Quaternary ammonium compounds (Quats), such as benzalkonium chloride, are a large group of related compounds. Some have been used as a low level disinfectant. They are effective against bacteria, but not against some species of Pseudomonas bacteria or bacterial spores. Quats are biocides which also kill algae and are used as an additive in large-scale industrial water systems to minimize undesired biological growth. Quaternary ammonium compounds can be effective disinfectants against enveloped viruses.

Other

- *Dettol* is used to disinfect surfaces at home. It kills the majority of bacteria. It is one of the few disinfectants useful against viruses.
- *Virkon* is a wide-spectrum disinfectant used in labs. It kills bacteria, viruses, and fungi. It is used as a 1% solution in water, and keeps for one week once it is made up. It is expensive, but very effective, its pink colour fades as it is used up so it is possible to see at a glance if it is still fresh.
- *High-intensity ultraviolet light* can be used for disinfecting smooth surfaces such as dental tools, but not porous materials that are opaque to the light

such as wood or foam. Ultraviolet light fixtures are often present in microbiology labs, and are activated only when there are no occupants in a room (e.g., at night.

Relative effectiveness of disinfectants

One way to compare disinfectants is to compare how well they do against a known disinfectant and rate them accordingly. Phenol is the standard, and the corresponding rating system is called the "Phenol coefficient". The disinfectant to be tested is compared with phenol on a standard microbe (usually Salmonella typhi or Staphylococcus aureus). Disinfectants that are more effective than phenol have a coefficient > 1. Those that are less effective have a coefficient < 1.

Home Disinfectants

By far the most cost-effective home disinfectant is common chlorine bleach (a 5% solution of Sodium hypochlorite which is effective against most common pathogens, including such difficult organisms as HIV, tuberculosis (mycobacterium tuberculosis), hepatitis B and C,funguses, and antibiotic-resistant strains of staphylococcus and enterococcus. It even has some disinfectant action against parasitic organisms [1]. Positives are that it kills the widest range of pathogens of any inexpensive disinfectant; it is extremely powerful against viruses and bacteria at room temperature; it is commonly available and inexpensive; and it breaks down quickly into harmless components (primarily table salt and oxygen). Negatives are that it is caustic to the skin and eyes, especially at higher concentrations; like many common disinfectants, it degrades in the presence of organic substances; it smells bad; it is not effective against giardia lamblia and cryptosporidium; and extreme caution must be taken not to combine it with ammonia or any acid (such as vinegar). The best practice is not to add anything to household bleach except water. Dilute bleach can be tolerated on the skin for a period of time by most persons, as witnessed by the long exposure to extremely dilute "chlorine" (actually sodium or calcium hypochlorite) many children get in swimming pools.

To use chlorine bleach effectively, the surface or item to be disinfected must be clean. In the bathroom, special caution must be taken to wipe up urine. A 1 to 20 solution in water is effective simply by being wiped on and left to dry. The user should wear rubber gloves and, in tight airless spaces, goggles. If parasitic organisms are suspected, it should be applied at 1 to 1 concentration, or even undiluted; extreme caution must be taken to avoid contact with eyes and mucous membranes. Protective goggles and good ventilation are mandatory when applying concentrated bleach.

Where one does not want to risk the corrosive effects of bleach, alcohol-based disinfectants are reasonably inexpensive and quite safe. The great drawback to them is their rapid evaporation; sometimes effective disinfection can be obtained only by immersing an object in the alcohol.

Bleach

To *bleach* something is to remove or lighten its color; a "bleach" is a chemical that can produce these effects, often via oxidation. Common chemical bleaches include a solution of sodium hypochlorite (NaOCl), or "chlorine bleach," and "oxygen bleach," which contains hydrogen peroxide or a peroxide-releasing compound such as sodium perborate or sodium percarbonate. "Bleaching powder" is calcium hypochlorite. Bleaching may be a preliminary step in the process of dyeing.

Types of bleach

Household bleach, also known as *chlorine bleach*, sodium hypochlorite (NaClO), has a pH level of 11 and is used in the home for whitening clothes, removing stains, and disinfecting. This is because sodium hypochlorite yields chlorine radicals—oxidizing agents readily reacting with many substances.

Chlorine bleach is often used with laundry detergents and is also commonly used as a disinfectant. Mixing bleach and cleaners containing ammonia, or using bleach to clean up urine can create toxic chloramine gases and an explosive called nitrogen trichloride.

Hair bleach contains H2O2 (hydrogen peroxide), which gives off oxygen radicals as it decomposes. Oxygen and chlorine radicals both have comparable bleaching effects.

Various other peroxide yielding chemicals are used as bleaching additives. Sodium perborate, sodium percarbonate, sodium persulfate, sodium perphosphate, sodium persilicate, their ammonium, potassium and lithium analogs, calcium peroxide, zinc peroxide, sodium peroxide, carbamide peroxide, and others are commonly used in detergents, toothpastes, and other products.

Chlorine dioxide is used for the bleaching of wood pulp, fats and oils, cellulose, flour, textiles, beeswax, and in a number of other industries.

In the food industry, some organic peroxides (benzoyl peroxide, etc.) and other agents (e.g. bromates) are used as flour bleaching and maturing agents.

Not all bleaches have to be of oxidizing nature. Sodium dithionite is used as a powerful reducing agent in some bleaching formulas.

How bleaches work

Color in most dyes and pigments is produced by molecules, such as beta carotene, that contain moieties (pieces) known as chromophores. Chemical bleaches work in one of two ways:

- An oxidizing bleach works by breaking the chemical bonds that make up the chromophore. This changes the molecule into a different substance that either does not contain a chromophore, or contains a chromophore that does not absorb visible light.
- A reducing bleach works by converting double bonds in the chromophore into single bonds. This eliminates the ability of the chromophore to absorb visible light.[1]

Sunlight acts as a bleach through a process leading to similar results: high energy photons of light, often in the violet or ultraviolet range, can disrupt the bonds in the chromophore, rendering the resulting substance colorless. [2]

Hazards

A problem with chlorine is that it reacts with organic material to form trihalomethanes like chloroform, which is a well known carcinogen. There is debate over whether any risk from the chloroform in treated drinking water is worth the benefits. However, the use of elemental chlorine in industrial processes such as paper bleaching, with its attendant production of organochlorine-persistent organic pollutants (including dioxins), does not have any benefits. As a consequence over 80 % of the woodpulp is nowadays bleached with chlorine dioxide, reducing the dioxin generation under detectable levels.

Chlorine is a respiratory irritant. It also attacks mucus membranes and burns the skin. As little as 3.5 ppm can be detected as an odor, and 1000 ppm is likely to be fatal after a few deep breaths. Exposure to chlorine should not exceed 0.5 ppm (8-hour time-weighted average - 40 hour week).

Another hazard is the formation of acrid chloramine fumes when hypochlorite bleach comes into contact with ammonia or urine, which, though not nearly as dangerous as chlorine, can cause severe respiratory distress.

Chlorine dioxide is a reddish-yellow gas which is one of several known oxides of chlorine. Chlorine dioxide is not stable in the gas state above 15% volume in air at STP (115 mm Hg) and can spontaneously and explosively decompose into chlorine and oxygen. Practically, it is never handled in its pure (concentrated) form. It is almost always used as a dissolved gas in water in a concentration range of 0.5 to 10 grams/liter. Chlorine dioxide is inversely soluble with temperature. In order to keep chlorine dioxide in solution, it is common to used chilled water (5°C or 41°F) when storing at concentrations above 3 grams/liter. In many countries, such as the USA, chlorine dioxide gas may not be transported at any concentration and is almost always produced at the application site using a chlorine dioxide generator. In some countries, chlorine dioxide solution below 3 grams/liter in concentration may be transported by land, but are relatively unstable and deteriorate quickly.

A number of products are marketed as "stabilized chlorine dioxide" (SCD). These are not actually solutions of chlorine dioxide but solutions of buffered sodium chlorite. A weak acid can be added to SCD to "activate" it and make chlorine dioxide in-situ without a chlorine dioxide generator. The use of SCD is effective when the demand for chlorine dioxide is low and when impurities, such as small amounts of chlorine, can be tolerated. For application requiring above 5 kg day1 ClO***2***, chlorine dioxide produced by a generator with either sodium chlorite or sodium chlorate is typically more economical.

Uses

Chlorine dioxide is used primarily (>95%) for bleaching of wood pulp, but is also used for the bleaching of flour and for the disinfection of water. The Niagara Falls, New York water treatment plant first used chlorine dioxide for drinking water treatment in 1944 for phenol destruction. Chlorine dioxide was introduced as a drinking water disinfectant on a large scale in 1956, when Brussels, Belgium, changed from chlorine to chlorine dioxide. Its most common use in water treatment is as a pre-oxidant prior to chlorination of drinking water to reduce trihalomethanes which are a carcinogenic disinfection by-product associated with chlorination of naturally occurring organics in the raw water. Chlorine dioxide is also used in conjunction with ozone disinfection of water to reduce the formation of bromates which are regulated carcinogens. Chlorine dioxide is also superior to chlorine when operating above neutral pH, when ammonia is present and for the control of biofilms. Chlorine dioxide is used in many industrial water treatment applications as a biocide including cooling towers, process water and food processing. Chlorine dioxide is less corrosive than chlorine and superior for the control of legionella bacteria.

It is more effective than chlorine against viruses, bacteria and protozoa – including the cysts of Giardia and the oocysts of Cryptosporidium.

It can also be used for air disinfection, and was the principal agent used in the decontamination of buildings in the United States after the 2001 anthrax attacks. Recently, after the disaster of Hurricane Katrina in New Orleans, Louisiana and the surrounding Gulf Coast, chlorine dioxide has been used to eradicate dangerous mold from houses inundated by water from massive flooding.

Chlorine dioxide is used as an oxidant for phenol destruction in waste water streams, control of zebra mussels in water intakes and for odor control in the air scrubbers of animal byproduct (rendering) plants.

Preparation

Chlorine dioxide can be produced with high efficiency by reducing sodium chlorate in a strong acid solution with a suitable reducing agent (for example, hydrogen peroxide, sulfur dioxide, or hydrochloric acid):

2ClO***3*** + 2Cl + 4H+ ’ 2ClO***2*** + Cl***2*** + 2H***2***O

Over 95% of the chlorine dioxide produced in the world today is made via the sodium chlorate method for pulp bleaching.

A much smaller but important market for chlorine dioxide is for use as a disinfectant. Since 1999 a growing proportion of the chlorine dioxide made globally for water treatment and other small scale applications has been made using the chlorate, hydrogen peroxide and sulfuric acid method which can produce a chlorine free product at high efficiency.

Traditionally, chlorine dioxide for disinfection applications has been made by one of three methods using sodium chlorite:

sodium chlorite - chlorine gas method:

$2NaClO_2 + Cl_2$ ’ $2ClO_2 + 2NaCl$

or the sodium chlorite - hypochlorite method:

$2NaClO_2 + 2HCl + NaOCl$ ’ $2ClO_2 + 3NaCl + H_2O$

or the sodium chlorite - hydrochloric acid method:

$5NaClO_2 + 4HCl$ ’ $5NaCl + 4ClO_2$

All three sodium chlorite chemistries can produce chlorine dioxide with high chlorite conversion yield, but the chlorite-HCl method suffers from the requirement of 25% more chlorite to produce an equivlent amount of chlorine dioxide.

Chlorine dioxide can also be produced by electrolysis of a chlorite solution:

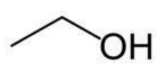
$2NaClO_2 + 2H_2O$ ’ $2ClO_2 + 2NaOH + H_2$

High purity chlorine dioxide gas (7.7% in air or nitrogen) can be produced by the Gas:Solid method, which reacts dilute chlorine gas with solid sodium chlorite.

$2NaClO_2 + Cl_2$ ’ $2ClO_2 + 2NaCl$

These processes and several slight variations are reviewed in Geo. Clifford White's Handbook of Chlorination and Alternative Disinfectants, 4th Edition (Wiley, 1999).

Ethanol



Systematic name Ethanol

Other names Ethyl alcohol, grain alcohol, hydroxyethane, EtOH

Molecular formula C_2H_6O

SMILES CCO

Molar mass 46.06844(232) g/mol

Appearance colourless clear liquid

CAS number [64-17-5]

Properties

Density and phase 0.789 g/cm^3, liquid

Solubility in water Fully miscible

Melting point 114.3 °C (158.8 K)

Boiling point 78.4 °C (351.6 K)

Acidity (p*Ka*) 15.9 (H± from OH group)

Viscosity 1.200 cP at 20 °C

Dipole moment 1.69 D (gas)

Hazards

MSDS External MSDS

EU classification Flammable (*F*)
R-phrases **R11**

S-phrases **S2**, **S7**, **S16**

Flash point 13 °C (55.4 °F)

RTECS number KQ6300000

Related compounds

Related alcohols Methanol, 1-Propanol

Other heteroatoms Ethylamine, Ethyl chloride, Ethyl bromide, Ethanethiol

Substituted ethanols Ethylene glycol, Ethanolamine, 2-Chloroethanol

Other compounds Acetaldehyde, Acetic acid

Except where noted otherwise, data are given for materials in their standard state (at 25°C, 100 kPa)

Ethanol, also known as *ethyl alcohol* or grain alcohol, is a flammable, colorless, mildly toxic chemical compound with a distinctive perfume-like odor, and is the alcohol found in alcoholic beverages. In common usage, it is often referred to simply as alcohol. Its molecular formula is variously represented as EtOH, C2H5OH or as its empirical formula C2H6O.

History

Ethanol has been used by humans since prehistory as the intoxicating ingredient in alcoholic beverages. Dried residues on 9000-year-old pottery found in northern mainland China imply the use of alcoholic beverages even among Neolithic peoples.[1] Its isolation as a relatively pure compound was first achieved by Persian alchemists who developed the art of distillation during the Abbasid caliphate, the most notable of whom was Al-Razi. The writings attributed to Jabir Ibn Hayyan (Geber) (721-815) mention the flammable vapors of boiled wine. Al-Kind+ (801-873) unambiguously described the distillation of wine.[2] Distillation of ethanol from water yields a product that is at most 95.6% ethanol, because ethanol forms an azeotrope with water. Absolute ethanol was first obtained in 1796 by Johann Tobias Lowitz, by filtering distilled ethanol through charcoal.

Antoine Lavoisier described ethanol as a compound of carbon, hydrogen, and oxygen, and in 1808, Nicolas-Théodore de Saussure determined ethanol's chemical formula, and fifty years later, in 1858, Archibald Scott Couper published a structural formula for ethanol: this places ethanol among the first chemical compounds to have their chemical structures determined.[3]

Ethanol was first prepared synthetically in 1826, through the independent efforts of Henry Hennel in Great Britain and S.G. Sérullas in France. Michael Faraday prepared ethanol by the acid-catalysed hydration of ethylene in 1828, in a process similar to that used for industrial ethanol synthesis today.[4]

Ethanol served as lamp fuel in pre-Civil War United States and helped power early Model T automobiles. But the fuel couldn't compete with the low cost and availability of petroleum, and ethanol faded from the public eye. The recent rise in oil prices has spurred renewed interest.[5]

Physical properties

Ethanol's hydroxyl group is able to participate in hydrogen bonding. At the molecular level, liquid ethanol consists of hydrogen-bonded pairs of ethanol molecules; this phenomenon renders ethanol more viscous and less volatile than less polar organic compounds of similar molecular weight. In the vapor phase, there is little hydrogen bonding; ethanol vapor consists of individual ethanol molecules.

Ethanol has a refractive index of 1.3614.

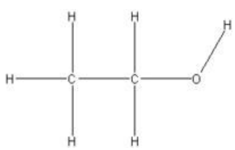
Ethanol is a versatile solvent. It is miscible with water and with most organic liquids, including nonpolar liquids such as aliphatic hydrocarbons. Organic solids of low molecular weight are usually soluble in ethanol. Among ionic compounds, many monovalent salts are at least somewhat soluble in ethanol, with salts of large, polarizable ions being more soluble than salts of smaller ions. Most salts of polyvalent ions are practically insoluble in ethanol.

Furthermore, ethanol is used as a solvent in dissolving medicines, food flavourings and colourings that do not dissolve easily in water. Once the non-polar material is dissolved in the ethanol, water can be added to prepare a solution that is mostly water. The ethanol molecule has a water-loving (hydrophilic) -OH group that helps it dissolve polar molecules and ionic substances. The short, water-fearing (hydrophobic) hydrocarbon chain CH_3CH_2-

can attract non-polar molecules. Thus ethanol can dissolve both polar and non-polar substances.

Several unusual phenomena are associated with mixtures of ethanol and water. Ethanol-water mixtures have less volume than their individual components: a mixture of equal volumes ethanol and water has only 95.6% of the volume of equal parts ethanol and water, unmixed. The addition of even a few percent of ethanol to water sharply reduces the surface tension of water. This property partially explains the tears of wine phenomenon: when wine is swirled inside a glass, ethanol evaporates quickly from the thin film of wine on the wall of the glass. As its ethanol content decreases, its surface tension increases, and the thin film beads up and runs down the glass in channels rather than as a smooth sheet.

Chemistry



Chemical formula of ethanol, (C is carbon, the dash is a single bond, H is hydrogen, O is oxygen)

The chemistry of ethanol is largely that of its hydroxyl group.

Acid-base chemistry

Ethanol's hydroxyl proton is very weakly acidic; it is an even weaker acid than water. Ethanol can be quantitatively converted to its conjugate base, the ethoxide ion (CH3CH2O), by reaction with an alkali metal such as sodium. This reaction evolves hydrogen gas:

$2CH_3CH_2OH + 2Na$ ’ $2CH_3CH_2ONa + H_2$

Nucleophilic substitution

In aprotic solvents, ethanol reacts with hydrogen halides to produce ethyl halides such as ethyl chloride and ethyl bromide via nucleophilic substitution:

$CH_3CH_2OH + HCl$ ’ $CH_3CH_2Cl + H_2O$ $CH_3CH_2OH + HBr$ ’ $CH_3CH_2Br + H_2O$

Ethyl halides can also be produced by reacting ethanol by more specialized halogenating agents, such as thionyl chloride for preparing ethyl chloride, or phosphorus tribromide for preparing ethyl bromide.

Esterification

Under acid-catalysed conditions, ethanol reacts with carboxylic acids to produce ethyl esters and water:

$RCOOH + HOCH_2CH_3$ ’ $RCOOCH_2CH_3 + H_2O$

The reverse reaction, hydrolysis of the resulting ester back to ethanol and the carboxylic acid, limits the extent of reaction, and high yields are unusual unless water can be removed from the reaction mixture as it is formed. Esterification can also be carried out using more a reactive derivative of the carboxylic acid, such as an acyl chloride or acid anhydride.

Ethanol can also form esters with inorganic acids. Diethyl sulfate and triethyl phosphate, prepared by reacting ethanol with sulfuric and phosphoric acid, respectively, are both useful ethylating agents in organic synthesis. Ethyl nitrite, prepared from the reaction of ethanol with sodium nitrite and sulfuric acid, was formerly a widely-used diuretic.

Dehydration

Strong acids, such as sulfuric acid, can catalyse ethanol's dehydration to form either diethyl ether or ethylene:

2 CH_3CH_2OH ’ $CH_3CH_2OCH_2CH_3 + H_2O$ CH_3CH_2OH ’ $H_2C=CH_2 + H_2O$

Which product, diethyl ether or ethylene, predominates depends on the precise reaction conditions.

Oxidation

Ethanol can be oxidized to acetaldehyde, and further oxidized to acetic acid. In the human body, these oxidation reactions are catalysed by enzymes. In the laboratory, aqueous solutions of strong oxidizing agents, such as chromic acid or potassium permanganate, oxidize ethanol to acetic acid, and it is difficult to stop the reaction at acetaldehyde at high yield. Ethanol can be oxidized to acetaldehyde, without overoxidation to acetic acid, by reacting it with pyridinium chromic chloride.

Combustion

Combustion of ethanol forms carbon dioxide and water:

$C_2H_5OH + 3\ O_2$ ’ $2\ CO_2 + 3\ H_2O$

Production

Ethanol is produced both as a petrochemical, through the hydration of ethylene, and biologically, by fermenting sugars with yeast.

Ethylene hydration

Ethanol for use as industrial feedstock is most often made from petrochemical feedstocks, typically by the acid-catalyzed hydration of ethene, represented by the chemical equation

C2H4 + H2O ’ CH3CH2OH

The catalyst is most commonly phosphoric acid, adsorbed onto a porous support such as diatomaceous earth or charcoal; this catalyst was first used for large-scale ethanol production by the Shell Oil Company in 1947.[6] Solid catalysts, mostly various metal oxides, have also been mentioned in the chemical literature.

In an older process, first practiced on the industrial scale in 1930 by Union Carbide,[7] but now almost entirely obsolete, ethene was hydrated indirectly by reacting it with concentrated sulfuric acid to product ethyl sulfate, which was then hydrolysed to yield ethanol and regenerate the sulfuric acid:

C2H4 + H2SO4 ’ CH3CH2SO4H CH3CH2SO4H + H2O ’ CH3CH2OH + H2SO4

Fermentation

Ethanol for use in alcoholic beverages, and the vast majority of ethanol for use as fuel, is produced by fermentation: when certain species of yeast (most importantly, Saccharomyces cerevisiae) metabolize sugar in the absence of oxygen, they produce ethanol and carbon dioxide. The overall chemical reaction conducted by the yeast may be represented by the chemical equation

C6H12O6 ’ 2 CH3CH2OH + 2 CO2

The process of culturing yeast under conditions to produce alcohol is referred to as brewing. Brewing can only produce relatively dilute concentrations of ethanol in water; concentrated ethanol solutions are toxic to yeast. The most ethanol-tolerant strains of yeast can survive in up to about 25% ethanol (by volume).

During the fermentation process, it is important to prevent oxygen getting to the ethanol, since otherwise the ethanol would be oxidised to acetic acid (vinegar). Also, in the presence of oxygen, the yeast would undergo aerobic respiration to produce just carbon dioxide and water, without producing ethanol.

In order to produce ethanol from starchy materials such as cereal grains, the starch must first be broken down into sugars. In brewing beer, this has traditionally been accomplished allowing the grain to germinate, or malt. In the process of germination, the seed produces enzymes that can break its starches into sugars. For fuel ethanol, this hydrolysis of starch into glucose is accomplished more rapidly by treatment with dilute sulfuric acid, fungal amylase enzymes, or some combination of the two.

At petroleum prices like those that prevailed through much of the 1990s, ethylene hydration was a decidedly more economical process than fermentation for producing purified ethanol. Recent increases in petroleum prices, coupled with perennial uncertainty in agricultural prices, make forecasting the relative production costs of fermented versus petrochemical ethanol difficult at the present time.

Purification

The product of either ethylene hydration or brewing is an ethanol-water mixture. For most industrial and fuel uses, the ethanol must be purified. Fractional distillation can concentrate ethanol to 95.6% volume; the mixture of 95.6% ethanol and 4.4% water (percentage by weight) is an azeotrope with a boiling point of 78.2 °C, and cannot be further purified by distillation. Therefore, 95% ethanol in water is a fairly common solvent.

After distillation ethanol can be further purified by "drying" it using lime or salt. Lime, (calcium oxide), when mixed with the water in ethanol will form calcium hydroxide, which then can be separated. Dry salt will dissolve some of the water content of the ethanol as it passes through, leaving a purer alcohol.[8]

Several approaches are used to produce absolute ethanol. The ethanol-water azeotrope can be broken by the addition of a small quantity of benzene. Benzene, ethanol, and water form a ternary azeotrope with a boiling point of 64.9 °C. Since this azeotrope is more volatile than the ethanol-water azeotrope, it can be fractionally distilled out of the ethanol-water mixture, extracting essentially all of the water in the process. The bottoms from such a distillation is anhydrous ethanol, with several parts per million residual benzene. Benzene is toxic to humans, and cyclohexane has largely supplanted benzene in its role as the entrainer in this process.

Alternatively, a molecular sieve can be used to selectively absorb the water from the 95.6% ethanol solution. Synthetic zeolite in pellet form can be used, as well as a variety of plant-derived absorbents, including cornmeal, straw, and sawdust. The zeolite bed can be regenerated essentially an unlimited number of times by drying it with a blast of hot carbon dioxide. Cornmeal and other plant-derived absorbents cannot readily be regenerated, but where ethanol is made from grain, they are often available at low cost. Absolute ethanol produced this way has no residual benzene, and can be used as fuel, or, when diluted, can even be used to fortify port and sherry in traditional winery operations.

At pressures less than atmospheric pressure, the composition of the ethanol-water azeotrope shifts to more ethanol-rich mixtures, and at pressures less than 70 torr (9.333 kPa) , there is no azeotrope, and it is possible to distill absolute ethanol from an ethanol-water mixture. While vacuum distillation of ethanol is not presently economical, pressure-swing distillation is a topic of current research. In this technique, a reduced-pressure distillation first yields an ethanol-water mixture of more than 95.6% ethanol. Then, fractional distillation of this mixture at atmospheric pressure distills off the 95.6% azeotrope, leaving anhydrous ethanol at the bottoms.

Prospective technologies

Glucose for fermentation into ethanol can also be obtained from cellulose. Until recently, however, the cost of the cellulase enzymes that could hydrolyse cellulose has been prohibitive. The Canadian firm Iogen brought the first cellulose-based ethanol plant on-stream in 2004.[9] The primary consumer thus far has been the Canadian government, which, along with the United States government (particularly the Department of Energy's National Renewable Energy Laboratory), has invested millions of dollars into assisting the commercialization of cellulosic ethanol. Realization of this technology would turn a number of cellulose-containing agricultural byproducts, such as corncobs, straw, and sawdust, into renewable energy resources.

Cellulosic materials typically contain, in addition to cellulose, other polysaccharides, including hemicellulose. When hydrolysed, hemicellulose breaks down into mostly five-carbon sugars such as xylose. S. cerevisiae, the yeast most commonly used for ethanol production, cannot metabolize xylose. Other yeasts and bacteria are under investigation to metabolize xylose and so improve the ethanol yield from cellulosic material.[10][11]

The anaerobic bacterium Clostridium ljungdahlii, recently discovered in commercial chicken wastes, can produce ethanol from single-carbon sources including synthesis gas, a mixture of carbon monoxide and hydrogen that can be generated from the partial

combustion of either fossil fuels or biomass. Use of these bacteria to produce ethanol from synthesis gas has progressed to the pilot plant stage at the BRI Energy facility in Fayetteville, Arkansas;[12] in the BRI process, the heat released by gasification can be used to co-produce electricity with ethanol.

Another prospective technology is the closed-loop ethanol plant. Ethanol produced from corn has a number of critics who suggest that it is primarily just recycled fossil fuels because of the energy required to grow the grain and convert it into ethanol. However, the closed-loop ethanol plant attempts to address this criticism. In a closed-loop plant, the energy for the distillation comes from fermented manure, produced from cattle that have been fed the by-products from the distillation. The leftover manure is then used to fertilize the soil used to grow the grain. Such a process is expected to have a much lower fossil fuel requirement.[13]

Ethanol

Denatured alcohol

In most jurisdictions, the sale of ethanol, as a pure substance, or in the form of alcoholic beverages, is heavily taxed. In order to relieve non-beverage industries of this tax burden, governments specify formulations for denatured alcohol, which consists of ethanol blended with various additives to render it unfit for human consumption. These additives, called denaturants, are generally either toxic (such as methanol) or have unpleasant tastes or odors (such as denatonium benzoate).

Specialty denatured alcohols are denatured alcohol formulations intended for a particular industrial use, containing denaturants chosen so as not to interfere with that use. While they are not taxed, purchasers of specialty denatured alcohols must have a government-issued permit for the particular formulation they use and must comply with other regulations.

Completely denatured alcohols are formulations that can be purchased for any legal purpose, without permit, bond, or other regulatory compliance. It is intended that it be difficult to isolate a product fit for human consumption from completely denatured alcohol. For example, the completely denatured alcohol formulation used in the United Kingdom contains (by volume) 89.66% ethanol, 9.46% methanol, 0.50% pyridine, 0.38% naphtha, and is dyed purple with methyl violet.[14]

Hydrous and anhydrous ethanol

Hydrous and anhydrous ethanol are terms used to describe ethanol by the type of process used to covert biomass into fuel. There are different prices for each anhydrous and hydrous ethanol depending on market demands.

The term hydrous pyrolysis is sometimes used to encompass thermolysis in the presence of water, such as steam cracking of oil, or more generally hydrous pyrolysis. An example of the latter is thermal depolymerization of organic waste into light crude oil.

Anhydrous (without water) pyrolysis can be used to produce liquid fuel similar to diesel from solid biomass. The most common technique uses very low residence times (<2 seconds) and high heating rates using a temperature between 350-500 °C. It is called either fast or flash pyrolysis.'

Anhydrous Alcohol can also be produced from hydrous(95-96%) alcohol using drying agents like molecular sieves, or by azeotropic distillation, extractive distillation techniques.

Absolute ethanol

Absolute or anhydrous alcohol generally refers to purified ethanol, containing no more than one percent water.

It is not possible to obtain absolute alcohol by simple fractional distillation, because a mixture containing around 95.6% alcohol and 4.4% water becomes a constant boiling mixture (an azeotropic mixture). In one common industrial method to obtain 100% pure alcohol, a small quantity of benzene is added to rectified spirit and the mixture is then distilled. Absolute alcohol is obtained in third fraction that distills over at 78.2 °C (351.3 K).

Because a small amount of the benzene used remains in the solution, absolute alcohol produced by this method is not suitable for consumption as benzene is carcinogenic.

There is also an absolute alcohol production process by desiccation using glycerol. Alcohol produced by this method is known as spectroscopic alcohol - so called because the absence of benzene makes it suitable as a solvent in spectroscopy.

Currently, the most popular method of purification past 95.6% purity is desiccation using adsorbents such as starch or zeolites. These adsorb water preferentially.

Feedstocks

Currently the main feedstock in the United States for the production of ethanol is corn (see the Renewable Fuels Association's list of U.S. ethanol for a complete list and feedstock utilized[1]).

Trials of a new crop, switchgrass, are showing much greater yields.

The dominant ethanol feedstock in warmer regions is sugarcane.

In some parts of Europe, particularly France and Italy, wine is used as a feedstock due to massive oversupply.

Use

As a fuel

The largest single use of ethanol is as a motor fuel and fuel additive. The largest national fuel ethanol industries exist in Brazil (all fuel sold in Brazil contains at least 20% ethanol).[15] One method of production is through fermentation of sugar. Ethanol creates very little pollution when being burned.However, the production process is actually more detrimental to the environment. Millions more acres of land are needed if ethanol is to be used to replace gasoline. It has a lower energy content than gasoline.[16][17] At gas stations,

ethanol is contained in a mix of ethanol and gasoline, otherwise known as gasahol. In the United States, the color yellow (symbolizing the color of corn) has become associated with the fuel and is commonly used on fuel pumps and labels.

Alcoholic beverages

Alcoholic beverages vary considerably in their ethanol content and in the foodstuffs from which they are produced. Most alcoholic beverages can be broadly classified as fermented beverages, beverages made by the action of yeast on sugary foodstuffs, or as distilled beverages, beverages whose preparation involves concentrating the ethanol in fermented beverages by distillation. The ethanol content of a beverage is usually measured in terms of the volume fraction of ethanol in the beverage, expressed either as a percentage or in alcoholic proof units.

Fermented beverages can be broadly classified by the foodstuff from which they are fermented. Beers are made from cereal grains or other starchy materials, wines and ciders from fruit juices, and meads from honey. Cultures around the world have made fermented beverages from numerous other foodstuffs, and local and national names for various fermented beverages abound. Fermented beverages may contain up to 15–20% ethanol by volume, the upper limit being set by the yeast's tolerance for ethanol, or by the amount of sugar in the starting material.

Distilled beverages are made by distilling fermented beverages. Broad categories of distilled beverages include whiskies, distilled from fermented cereal grains; brandies, distilled from fermented fruit juices, and rum, distilled from fermented molasses or sugarcane juice. Vodka and similar neutral grain spirits can be distilled from any fermented material (grain or potatoes is most common); these spirits are so thoroughly distilled that no tastes from the particular starting material remain. Numerous other spirits and liqueurs are prepared by infusing flavors from fruits, herbs, and spices into distilled spirits. A traditional example is gin, the infusion of juniper berries into neutral grain alcohol.

In a few beverages, ethanol is concentrated by means other than distillation. Applejack is traditionally made by freeze distillation: water is frozen out of fermented apple cider, leaving a more ethanol-rich liquid behind. Fortified wines are prepared by adding brandy or some other distilled spirit to partially-fermented wine. This kills the yeast and conserves some of the sugar in grape juice; such beverages are not only more ethanol-rich, but also sweeter than other wines.

Chemicals derived from ethanol

Ethyl esters

In the presence of an acid catalyst (typically sulfuric acid) ethanol reacts with carboxylic acids to produce ethyl esters:

CH*3*CH*2*OH + RCOOH ’ RCOOCH*2*CH*3* + H*2*O

The two largest-volume ethyl esters are ethyl acrylate (from ethanol and acrylic acid) and ethyl acetate (from ethanol and acetic acid). Ethyl acrylate is a monomer used to prepare acrylate polymers for use in coatings and adhesives. Ethyl acetate is a common solvent used in paints, coatings, and in the pharmaceutical industry; its most familiar application in the household is as a solvent for nail polish. A variety of other ethyl esters are used in much smaller volumes as artificial fruit flavorings.

Vinegar

Vinegar is a dilute solution of acetic acid prepared by the action of Acetobacter bacteria on ethanol solutions. Although traditionally prepared from alcoholic beverages including wine, apple cider, and unhopped beer, vinegar can also be made from solutions of industrial ethanol. Vinegar made from distilled ethanol is called "distilled vinegar", and is commonly used in food pickling and as a condiment.

Ethylamines

When heated to 150–220 °C over a silica- or alumina-supported nickel catalyst, ethanol and ammonia react to produce ethylamine. Further reaction leads to diethylamine and triethylamine:

- CH3CH2OH + NH3 ’ CH3CH2NH2 + H2O

CH3CH2OH + CH3CH2NH2 ’ (CH3CH2)2NH + H2O

CH3CH2OH + (CH3CH2)2NH ’ (CH3CH2)3N + H2O

The ethylamines find use in the synthesis of pharmaceuticals, agricultural chemicals, and surfactants.

Other chemicals

Ethanol is cool, and in the past has been used commercially to synthesize dozens of other high-volume chemical commodities. At the present, it has been supplanted in many applications by less costly petrochemical feedstocks. However, in markets with abundant agricultural products, but a less developed petrochemical infrastructure, such as the People's Republic of China, Pakistan, India, and Brazil, ethanol can be used to produce chemicals that would be produced from petroleum in the West, including ethylene and butadiene.

Other uses

Ethanol is easily soluble in water in all proportions with a slight overall decrease in volume when the two are mixed. Absolute ethanol and 95% ethanol are themselves good solvents, somewhat less polar than water and used in perfumes, paints and tinctures. Other proportions of ethanol with water or other solvents can also be used as a solvent. Alcoholic drinks have a large variety of tastes because various flavor compounds are dissolved during brewing. When ethanol is produced as a mixing beverage it is a neutral grain spirit.

Ethanol is used in medical wipes and in most common antibacterial hand sanitizer gels at a concentration of about 62% (percentage by weight, not volume) as an antiseptic. The peak of the disinfecting power occurs around 70% ethanol; stronger and weaker solutions of ethanol have a lessened ability to disinfect. Solutions of this strength are often used in laboratories for disinfecting work surfaces. Ethanol kills organisms by denaturing their proteins and dissolving their lipids and is effective against most bacteria and fungi, and many viruses, but is ineffective against bacterial spores. Alcohol does not act like an antibiotic and

is not effective against infections by ingestion. Ethanol in the low concentrations typically found in most alcoholic beverages does not have useful disinfectant or antiseptic properties, internally or externally.

Wine with less than 16% ethanol cannot protect itself against bacteria. Because of this, port is often fortified with ethanol to at least 18% ethanol by volume to halt fermentation for retaining sweetness and in preparation for aging, at which point it becomes possible to prevent the invasion of bacteria into the port, and to store the port for long periods of time in wooden containers that can 'breathe', thereby permitting the port to age safely without spoiling. Because of ethanol's disinfectant property, alcoholic beverages of 18% ethanol or more by volume can be safely stored for a very long time.

Metabolism and toxicology

Pure ethanol is a tasteless liquid with a strong and distinctive odor that produces a characteristic heat-like sensation when brought into contact with the tongue or mucous membranes. When applied to open wounds (as for disinfection) it produces a strong stinging sensation. Pure or highly concentrated ethanol may permanently damage living tissue on contact. Ethanol applied to unbroken skin cools the skin rapidly through evaporation.

In the human body, ethanol is first oxidized to acetaldehyde, and then to acetic acid. The first step is catalysed by the enzyme alcohol dehydrogenase, and the second by acetaldehyde dehydrogenase. Some individuals have less effective forms of one or both of these enzymes, and can experience more severe symptoms from ethanol consumption than others. Conversely, those who have acquired ethanol tolerance have a greater quantity of these enzymes, and metabolize ethanol more rapidly.

BAC (mg/dL), Symptoms

50: Euphoria, talkativeness, relaxation

100: Central nervous system depression, impaired motor and sensory function, impaired cognition

>140: Decreased blood flow to brain

300: Stupefaction, possible unconsciousness

400: Possible death

>550: Death highly likely[18]

The amount of ethanol in the body is typically quanitified by blood alcohol content (BAC), the milligrams of ethanol per 100 milliliters of blood. The table at right summarizes the symptoms of ethanol consumption. Small doses of ethanol generally produce euphoria and relaxation; people experiencing these symptoms tend to become talkative and less inhibited, and may exhibit poor judgment. At higher dosages (BAC > 0.10), ethanol acts as a central

nervous system depressant, producing at progressively higher dosages, impaired sensory and motor function, slowed cognition, stupefaction, unconsciousness, and possible death.

The initial product of ethanol metabolism, acetaldehyde, is more toxic than ethanol itself. The body can quickly detoxify some acetaldehyde by reaction with glutathione and similar thiol-containing biomolecules. When acetaldehyde is produced beyond the capacity of the body's glutathione supply to detoxify it, it accumulates in the bloodstream until further oxidized to acetic acid. The headache, nausea, and malaise associated with an alcohol hangover stem from a combination of dehydration and acetaldehyde poisoning; many health conditions associated with chronic ethanol abuse, including liver cirrhosis, alcoholism, and some forms of cancer, have been linked to acetaldehyde.[citation needed] The judicial system in the United States, in a number of jurisdictions, promoted the use of disulfiram, known as Antabuse, for persons convicted of driving while (alcohol) intoxicated. Disulfuram interferes with hepatic acetaldehyde metabolism, exacerbating the discomforts noted above. Numerous deaths, said to be related to disulfuram use, led to the elimination of these court-based programs. Some medications, including paracetamol (acetaminophen), as well as exposure to organochlorides, can deplete the body's glutathione supply, enhancing both the acute and long-term risks of even moderate ethanol consumption. Frequent use of alcoholic beverages has also been shown to be a major contributing factor in cases of elevated blood levels of triglycerides. [2]

Ethanol has been shown to increase the growth of Acinetobacter baumannii, a bacterium responsible for pneumonia, meningitis and urinary tract infections. This finding may contradict the common misconception that drinking alcohol could kill off a budding infection. (Smith and Snyder, 2005)

Hazards

- Ethanol-water solutions greater than about 50% ethanol by volume are flammable and easily ignited. Ethanol-water solutions below 50% ethanol by volume may also be flammable if the solution is vaporized by heating (as in some cooking methods that call for wine to be added to a hot pan, causing it to flash boil into a vapor, which is then ignited to "burn off" excessive alcohol).

Hypochlorous acid

Systematic name hypochlorous acid

Molecular formula HClO

Molar mass 52.46 g/mol

Appearance colorless aqueous solns

CAS number [7790-92-3]

Properties

Solubility in water soluble

Other solvents Et2O, CH2Cl2

Acidity (pK***a***) 7.53

Hazards

MSDS External MSDS

Main hazards oxidizer

Related compounds

Other anions NaOCl

Other cations HOBr, HOF

Related compounds Cl***2,*** Ca(OCl)$_2$

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Hypochlorous acid is a weak acid with the chemical formula HOCl. It forms when chlorine dissolves in water. It cannot be isolated in pure form due to rapid equilibration with its precursor (see below). HOCl is used as a bleach, an oxidizer, a deodorant, and a disinfectant.

Formation

Addition of chlorine to water gives both hypochlorous acid and hydrochloric acid (HCl):

$Cl_2 + H_2O$ ’ $HClO + HCl$

Chemical reactions

In aqueous solution, hypochlorous acid partially dissociates into the *hypochlorite anion* ClO^- (also known as the *chlorate(I) anion*) and the proton H^+. The salts of hypochlorous acid are also called *hypochlorites*. One of the best known hypochlorites is household bleach, sodium hypochlorite, NaClO.

In the presence of sunlight, hypochlorous acid decomposes into more hydrochloric acid and oxygen, so this reaction is sometimes seen as:

$2Cl_2 + 2H_2O$ ’ $4HCl + O_2$

HClO is considered to be a stronger oxidant than chlorine.

Uses

In organic synthesis, HOCl converts alkenes to chlorohydrins.[1]

In biology, hypochlorous acid is thought to be produced by neutrophils to kill bacteria, and it is the active sanitizer in all chlorine-based swimming pool products.

Safety

HOCl is a strong oxidant and thus can form explosive mixtures, and it can give off toxic chlorine gas.

Ozone (*O*3) is a triatomic molecule, consisting of three oxygen atoms. It is an allotrope of oxygen that is much less stable than the diatomic species O2. It is present in low concentrations throughout the Earth's atmosphere. It has many industrial and consumer applications as well as being used in ozone therapy.

Ozone, the first allotrope of a chemical element to be described by science, was discovered by Christian Friedrich Schönbein in 1840, who named it after the Greek word for smell (ozein), from the peculiar odor in lightning storms.[1] The odor from a lightning strike is from electrons freed during the rapid chemical changes, not the ozone itself.[2]

Physical properties

Undiluted ozone is a pale blue gas at standard temperature and pressure; it forms a dark blue liquid below 112 °C and a violet-black solid below 193 °C [3]. At concentrations found in the atmosphere it is colorless [4]. The concentration above which it can be smelt (odor threshold) is between 0.0076 and 0.036 ppm[5].

Chemistry

Ozone is a powerful oxidizing agent. It is also unstable at high concentrations, decaying to ordinary diatomic oxygen:

$2\ O_3$ ’ $3\ O_2$.

This reaction proceeds more rapidly with increasing temperature and decreasing pressure. Ozone will oxidize metals (except gold, platinum, and iridium) to oxides of the metals in their highest oxidation state:

$2\ Cu^{2+} + 2\ H^{+} + O_3$ ’ $2\ Cu^{3+} + H_2O + O_2$

Ozone converts oxides to peroxides:

$SO_2 + O_3$ ’ $SO_3 + O_2$

It also increases the oxidation number of oxides:

$NO + O_3$ ’ $NO_2 + O_2$

The above reaction is accompanied by chemiluminescence. The NO_2 can be further oxidized:

$NO_2 + O_3$ ’ $NO_3 + O_2$

The NO_3 formed can react with NO_2 to form N_2O_5:

$NO_2 + NO_3$ ’ N_2O_5

Ozone reacts with carbon to form carbon dioxide, even at room temperature:

$C + 2\ O_3$ ’ $CO_2 + 2\ O_2$

Ozone does not react with ammonium salts but it reacts with ammonia to form ammonium nitrate:

$2\ NH_3 + 4\ O_3$ ’ $NH_4NO_3 + 4\ O_2 + H_2O$

Ozone reacts with sulfides to make sulfates:

$PbS + 4\ O_3$ ’ $PbSO_4 + 4\ O_2$

Sulfuric acid can be produced from ozone, either starting from elemental sulfur or from sulfur dioxide:

$S + H_2O + O_3$ ’ H_2SO_4 $3\ SO_2 + 3\ H_2O + O_3$ ’ $3\ H_2SO_4$

All three atoms of ozone may also react, as in the reaction with tin(II) chloride and hydrochloric acid:

$3\ SnCl_2 + 6\ HCl + O_3$ ’ $3\ SnCl_4 + 3\ H_2O$

In the gas phase, ozone reacts with hydrogen sulfide to form sulfur dioxide:

$H_2S + O_3$ ’ $SO_2 + H_2O$

In an aqueous solution, however, two competing simultaneous reactions occur, one to produce elemental sulfur, and one to produce sulfuric acid:

$H_2S + O_3$ ’ $S + O_2 + H_2O$ $3\ H_2S + 4\ O_3$ ’ $3\ H_2SO_4$

Iodine perchlorate can be made by treating iodine dissolved in cold anhydrous perchloric acid with ozone:

$I_2 + 6\ HClO_4 + O_3$ ’ $2\ I(ClO_4)_3 + 3\ H_2O$

Solid nitryl perchlorate can be made from NO_2, ClO_2, and O_3 gases:

$2\ NO_2 + 2\ ClO_2\ 2\ O_3$ ’ $2\ NO_2ClO_4 + O_2$

Ozone can be used for combustion reactions and combusting gases in ozone provides higher temperatures than combusting in dioxygen (O2). Following is a reaction for the combustion of carbon subnitride:

$3\ C_4N_2 + 4\ O_3$ ’ $12\ CO + 3\ N_2$

Ozone can react at cryogenic temperatures. At 77 K (-196 °C), atomic hydrogen reacts with liquid ozone to form a hydrogen superoxide radical, which dimerizes[6]

$H + O_3$ ’ $HO_2 + O$ $2\ HO_2$ ’ H_2O_4

Ozonides can be formed, which contain the ozonide anion, O3-. These compounds are explosive and must be stored at cryogenic temperatures. Ozonides for all the alkali metals are known. KO_3, RbO_3, and CsO_3 can be prepared from their respective superoxides:

$KO_2 + O_3$ ’ $KO_3 + O_2$

Although KO_3 can be formed as above, it can also be formed from potassium hydroxide and ozone:[7]

$2\ KOH + 5\ O_3$ ’ $2\ KO_3 + 5\ O_2 + H_2O$

NaO_3 and LiO_3 must be prepared by action of CsO_3 in liquid NH_3 on an ion exchange resin containing Na± or Li± ions:[8]

CsO_3 + Na± ’ Cs± + NaO_3

Treatment with ozone of calcium dissolved in ammonia leads to ammonium ozonide and not calcium ozonide:[9]

3 Ca + 10 NH*3* + 6 O*3* ' Ca•6NH*3* + Ca(OH)*2* + Ca(NO*3*)*2* + 2 NH*4*O*3* + 2 O*2* + H*2*

Ozone can be used to remove manganese from the water, forming a precipitate which can be filtered:

2 Mn2+ + 2 O*3* + 4 H*2*O ' 2 MnO(OH)*2* *(s)* + 2 O*2* + 4 H+

Ozone will also turn cyanides to the one thousand times less toxic cyanates:

CN- + O*3* ' CNO- + O*2*

Finally, ozone will also completely decompose urea:[10]

(NH*2*)*2*CO + O*3* ' N*2* + CO*2* + 2 H*2*O

Ozone in Earth's atmosphere

The standard way to express total ozone amounts (the amount of ozone in a vertical column) in the atmosphere is by using Dobson units. Concentrations at a point are measured in parts per billion (ppb) or in ¼g/m^3.

Ozone layer

The highest levels of ozone in the atmosphere are in the stratosphere, in a region also known as the ozone layer between about 10 km and 50 km above the surface. Here it filters out the shorter wavelengths (less than 320 nm) of ultraviolet light (270 to 400 nm) from the Sun that would be harmful to most forms of life in large doses. These same wavelengths are also responsible for the production of vitamin D, which is essential for human health. Ozone in the stratosphere is mostly produced from ultraviolet rays reacting with oxygen:

O*2* + (radiation < 240 nm) ' 2 O O + O*2* ' O*3*

It is destroyed by the reaction with atomic oxygen:

O*3* + O ' 2 O*2*

The latter reaction is catalysed by the presence of certain free radicals, of which the most important are hydroxyl (OH), nitric oxide (NO) and atomic chlorine (Cl) and bromine (Br). In recent decades the amount of ozone in the stratosphere has been declining mostly due to emissions of CFCs and similar chlorinated and brominated organic molecules, which have increased the concentration of ozone-depleting catalysts above the natural background. For more information on stratospheric ozone see Seinfeld and Pandis (1999).

Low level ozone

Low level ozone (or tropospheric ozone) is regarded as a pollutant by the World Health Organisation[11]. It is not emitted directly by car engines or by industrial operations. It is formed by the reaction of sunlight on air containing hydrocarbons and nitrogen oxides that to form ozone directly at the source of the pollution or many kilometers down wind. For more details of the complex chemical reactions that produce low level ozone see tropospheric ozone or Seinfled and Pandis (1998).

Ozone reacts directly with some hydrocarbons such as aldehydes and thus begins their removal from the air, but the products are themselves key components of smog. Ozone photolysis by UV light leads to production of the hydroxyl radical and this plays a part in the removal of hydrocarbons from the air, but is also the first step in the creation of components of smog such as peroxyacyl nitrates which can be powerful eye irritants. The atmospheric lifetime of tropospheric ozone is about 22 days and its main removal mechanisms are being deposited to the ground, the above mentioned reaction giving OH, and by reactions with OH and the peroxy radical $HO_2\cdot$ (Stevenson et al, 2006) [12].

As well as having impact on human health (see below) there is also evidence of significant reduction in agricultural yields due to increased ground-level ozone and pollution which interferes with photosynthesis and stunts overall growth of some plant species.[13][14]

Ozone as a greenhouse gas

Although ozone was present at ground level before the industrial revolution, peak concentrations are far higher than the pre-industrial levels and even background concentrations well away from sources of pollution are substantially higher.[15][16] This increase in ozone is of further concern as ozone present in the upper troposphere acts as a greenhouse gas, absorbing some of the infrared energy emitted by the earth. Quantifying the greenhouse gas potency of ozone is difficult as it is not present in uniform concentrations across the globe. However, the most recent scientific review on the climate change (the IPCC Third Assessment Report[17]) suggests that the radiative forcing of tropospheric ozone is about 25% that of carbon dioxide.

Ozone and health

Ozone in air pollution

There is a great deal of evidence to show that high concentrations (ppm) of ozone, created by high concentrations of pollution and daylight UV rays at the earth's surface, can harm lung function and irritate the respiratory system [11][18]. There has also been shown to be a connection between increased ozone caused by thunderstorms and hospital admissions of asthma sufferers [19]. Air quality guidelines such as those from the World Health Organization are based on detailed studies of what levels can cause measurable health effects.

Physiology of ozone

Ozone, along with reactive forms of oxygen such as superoxide, singlet oxygen (see oxygen), hydrogen peroxide, and hypochlorite ions, is naturally produced by white blood cells and other biological systems (such as the roots of marigolds) as a means of destroying foreign bodies. Ozone reacts directly with organic double bonds. Also, when ozone breaks down to dioxygen it gives rise to oxygen free radicals, which are highly reactive and capable of damaging many organic molecules. Ozone has been found to convert cholesterol in the blood stream to plaque (which causes hardening and narrowing of arteries). Moreover, it is believed that the powerful oxidizing properties of ozone may be a contributing factor of inflammation. The cause-and-effect relationship of how the ozone is created in the body and what it does is still under consideration and still subject to various interpretations, since other body chemical processes can trigger some of the same reactions. A team headed by Dr. Paul Wentworth Jr. of the Department of Chemistry at the Scripps Research Institute has shown evidence linking the antibody-catalyzed water-oxidation pathway of the human immune response to the production of ozone. In this system, ozone is produced by antibody-catalyzed production of trioxidane from water and neutrophil-produced singlet oxygen. [20]. See also trioxidane for more on this biological ozone-producing reaction.

Ozone has also been proven to form specific, cholesterol-derived metabolites that are thought to facilitate the build-up and pathogenesis of atherosclerotic plaques (A form of heart disease). These metabolites have been confirmed as naturally occurring in human atherosclerotic arteries and are categorized into a class of secosterols termed “Atheronals”, generated by ozonolysis of cholesterol's double bond to form a 5,6 secosterol as well as a secondary condensation product via aldolization.[21] Volume: Number: Page: 23 DOI:

Safety

Artificial production

Ozone may be formed from O_2 by electrical discharges and by action of high energy electromagnetic radiation. Certain electrical equipment generate significant levels of ozone. This is especially true of devices using high voltages, such as laser printers, photocopiers, and arc welders. Electric motors using brushes can generate ozone from repeated sparking inside the unit. Large motors, such as those used by elevators or hydraulic pumps, will generate more ozone than smaller motors.

Industrial production

Ozone used in industry is measured in ppm or mg/L (OSHA exposure limits for example), and percent by mass or weight. Industrially, ozone is produced with short wavelength ultraviolet radiation from a mercury vapor lamp or the application of a high voltage electrical field in a process called cold or corona discharge. The cold discharge apparatus consists of two metal plates separated by an air gap and a high dielectric strength electrical insulator such as borosilicate glass or mica. A high voltage alternating current is applied to the plates and the ozone is formed in the air gap when O2 molecules disassociate and recombine into O3. A faint corona may be present in the air gap, but the voltage is maintained below that

which would cause punch-through of the insulator with subsequent arcing and plasma formation.

Laboratory production

In the laboratory ozone can be produced by electrolysis using a 9 volt battery, a pencil graphite rod cathode, a platinum wire anode and a 3M sulfuric acid electrolyte.[22] The half cell reactions taking place are:

3 H_2O ’ O_3 + 6 H^+ + 6 e ”E^o = 1.53 V 6 H^+ + 6 e ’ 3 H_2 ”E^o = 0 V 2 H_2O ’ O_2 + 4 H^+ + 4 e ”E^o = 1. 23 V

So that in the net reaction three equivalents of water are converted into one equivalent of ozone and three equivalents of hydrogen. Oxygen formation is a competing reaction.

Applications

Industrial applications

Ozone can be used for bleaching substances and for killing bacteria. Many municipal drinking water systems kill bacteria with ozone instead of the more common chlorine. Ozone does not form organochlorine compounds, but it also does not remain in the water after treatment, so some systems introduce a small amount of chlorine to prevent bacterial growth in the pipes, or may use chlorine intermittently, based on results of periodic testing. Where electrical power is abundant, ozone is a cost-effective method of treating water, as it is produced on demand and does not require transportation and storage of hazardous chemicals. Once it has decayed, it leaves no taste or odor in drinking water. Low level of Ozone is helpful to purify air inside the house. Eliminate mildew and mold build up.

Industrially, ozone or ozonated water is used to

- disinfect water before it is bottled;
- deodorize air and objects, such as after a fire;
- kill bacteria on food or on contact surfaces;
- scrub yeast and mold spores from the air in food processing plants;
- wash fresh fruits and vegetables to kill yeast, mold and bacteria;
- chemically attack contaminants in water (iron, arsenic, hydrogen sulfide, nitrites, and complex organics lumped together as "color");
- provide an aid to flocculation (agglomeration of molecules, which aids in filtration, where the iron and arsenic are removed);
- clean and bleach fabrics (the latter use is patented);
- assist in processing plastics to allow adhesion of inks;
- age rubber samples to determine the useful life of a batch of rubber;
- in surface water treatment plants to eradicate water borne parasites such as Giardia and Cryptosporidium. This process is known as ozonation.

Ozone is a reagent in many organic reactions in the laboratory and in industry. Ozonolysis is the cleavage of an alkene to carbonyl compounds.

Many hospitals in the U.S. and around the world use large ozone generators to decontaminate operating rooms between surgeries. The rooms are cleaned and then sealed airtight before being filled with ozone which effectively kills or neutralizes all remaining bacteria.

Consumer applications

Ozone machines, with or without ionization, are currently used to sanitize (high ozone output) and deodorize non-inhabited rooms, ductwork, vehicles, boats, woodsheds, and buildings.

Some models of air purifiers that also emit low levels of ozone have been sold in the US. These type of air purifiers claim to imitate nature's "filterless" air purifying mechanisms [23] and claim to "sanitize" the air and/or household surfaces. The government successfully sued one company in 1995, ordering them to stop repeating health claims without supporting scientific studies.

Ozonated water is used to launder clothes, sanitize food, drinking water, and surfaces in the home. According to the FDA, it is "amending the food additive regulations to provide for the safe use of ozone in gaseous and aqueous phases as an antimicrobial agent on food, including meat and poultry." Ironically, while ozone is considered an atmospheric pollutant, pollution and smog by the US government, it can actually reduce pollutants like pesticides in fruits and vegetables.[24]

Ozone is used in spas or hot tubs with reduced levels of Chlorine or Bromine for keeping the water free of bacteria. As it does not remain in the water after treatment, it is ineffective at preventing bather cross-contamination, and must be used in conjuction with another sanitizer. Ozone gas is created by an ultraviolet light bulb or corona discharge chip and injected into the plumbing system.

Ozone is also widely used in treatment of water in aquaria and fish ponds. Its use can minimise bacterial growth control parasites and removes or reduce "yellowing" of the water. As the Ozone rapidly decomposes, at correctly controlled levels the application has no effect on the fish.

Pharmaceutical applications

Ozone has a number of medical uses. It can be used to affect the body's antioxidant-prooxidant balance, since the body usually reacts to its presence by producing antioxidant enzymes.[citation needed] Ozone therapy has blossomed into a thriving field of alternative medicine, with a host of claimed applications far above and beyond what has actually been verified by studies .

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Potassium permanganate is the chemical compound KMnO4. In this salt, manganese is in the +7 oxidation state. The salt is also known as "permanganate of potash" and "Condy's crystals". The permanganate ion is a strong oxidizing agent. It dissolves in water to give deep purple solutions, evaporation of which gives prismatic purple-black glistening crystals.[1] It has a sweet taste and is odourless.

History

In 1659 a German chemist, J.R. Glauber, fused a mixture of the mineral pyrolusite and potassium carbonate to obtain a material that, when dissolved in water, gave a green solution (sodium manganate) which slowly changed colour to violet (*potassium permanganate*) and then finally red. This report represents the first description of the production of potassium permanganate.

Just under 200 years later a Londoner named Henry Bollmann Condy trained as a chemist. He had an interest in disinfectants and marketed a number of products including ozonised water. He found that when he fused pyrolusite with NaOH and dissolved the product in water it gave a solution that had good disinfectant properties. He patented this solution, and marketed it as Condy's Fluid. The problem was that the solution, although quite effective, was not very stable. This difficulty was overcome by using KOH rather than NaOH. This gave a more stable material, which had the added advantage of being easily converted to the equally effective potassium permanganate crystals. This crystalline material was known as Condy's crystals or Condy's powder. Potassium permanganate was comparatively easy to manufacture so Condy was subsequently forced to spend considerable time in litigation in order to stop competitors from marketing products similar to Condy's Fluid or Condy's Crystals.

Early photographers used it as a component of flash powder.

Uses

Chemical applications

Potassium permanganate is used as an oxidizing agent in diverse chemical reactions in the laboratory and in industry.[3] It also serves as a disinfectant and in deodorizers. It can be used as a reagent for the synthesis of many different kinds of chemical compounds. In wastewater treatment, it is used to neutralize hydrogen sulfide. In analytical chemistry, a standardized aqueous solution of $KMnO_4$ is sometimes used as an oxidizing titrant for redox titrations due to its deep purple color. In a related way, it is used as a reagent to determine the Kappa number of wood pulp. Mixing potassium permanganate and formaldehyde forms a mild tear gas.

As an oxidant in organic synthesis

Dilute solutions of $KMnO_4$ convert alkenes into diols (glycols). This behaviour is also used as a qualitative test for the presence of double or triple bonds in a molecule, since the reaction decolorizes the permanganate solution; thus it is sometimes referred to as Baeyer's reagent.

Concentrated solutions oxidize a methyl group on an aromatic ring, e.g. toluene to benzoic acid.

$KMnO_4$ oxidizes pseudoephedrine hydrochloride to produce methcathinone, a Schedule I drug in the United States. Consequently the DEA has restricted its use and sale by classifying it as a List I controlled precursor. Potassium permanganate is listed as a Table I precursor

under the United Nations Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances.[1]

Acids and KMnO4

diluted sulfuric acid reacts with KMnO4 to give Mn2O7, which can be explosive.[4][5][6]. Similarly concentrated HCl gives chlorine. The Mn-containing products from redox reactions depend on the pH. Acidic solutions of permanganate are reduced to the faintly pink [Mn(H2O)6]2+. In neutral solution, permanganate is only reduced by 5e- to give a soluton of Mn2+ (aq), wherein Mn is in a +2 oxidation state. This is the material that stains one's skin when handling KMnO4. KMnO4 spontaneously reduced in an alkaline solution to green-coloured K2MnO4, wherein manganese is in the +6 oxidation state.

A curious reaction is observed when one adds concentrated sulfuric acid to potassium permanganate. Although no reaction may be apparent, the vapor over the mixture will ignite paper impregnated with alcohol. Potassium permanganate and sulfuric acid react to produce some ozone, which has a high oxidising power and rapidly oxidises the alcohol, causing it to combust. An approximate equation for the ozone formation is shown below.

At room temperature 6 $KMnO_4(aq) + 9\ H_2SO_4(aq)$ ’ 6 $MnSO_4(aq) + 3\ K_2SO_4(aq) + 9\ H_2O(l) + 5\ O_3(g)$

Biomedical uses

- Dilute solutions are used as a treatment for canker sores (ulcers) (0.25%), disinfectant for the hands (about 1%) and treatment for mild pompholyx dermatitis or fungal infections of the hands or feet.
- A dilute solution of acidified potassium permanganate is used in histology to bleach melanin which obscures tissue detail.
- Potassium permanganate can be used to differentiate amyloid AA from other types of amyloid pathologically deposited in body tissues. Incubation of fixed tissue with potassium permanganate will prevent amyloid AA from staining with congo red whereas other types of amyloid are unaffected.[7][8]

Miscellaneous uses

- Aqueous solutions of $KMnO_4$ have been used together with T-Stoff (i.e. 80 % hydrogen peroxide) as propellant for the rocket plane Messerschmitt Me 163. In this application, it was known as Z-Stoff. This combination of propellants is still used in torpedoes.
- A dilute (10mg/l) of potassium permanganate can be used to eliminate snails from plants prior to placing them in a fresh-water aquarium.
- High-grade potassium permanganate can be found at pool supply stores and is used in rural areas to remove iron and hydrogen sulfide (rotten egg smell) from well water.

- $KMnO_4$ is often included in survival kits along with either glycerine or a glucose tablet for the purposes of making fire. The glucose tablet can be ground up, mixed with the potassium permanganate and caused to combust by applying friction. It can also be mixed with anti-freeze from a vehicle to produce flame, although this can be dangerous and should be done in a controlled manner ie dipping some paper into the anti-freeze and then adding a small amount of potassium permanganate. The ability to sterilise water and wounds is also advantageous and another reason for inclusion in a survival kit.
- $KMnO_4$ is employed to treat some parasitic diseases of fish, in treatment of drinking water, as well as an antidote in phosphorus poisoning. In Africa, it has been used as a disinfectant for vegetables such as lettuce.

Hazards

Solid $KMnO_4$ is a strong oxidizer and in general it should be kept separated from oxidisible substances. For more information consult an MSDS. Some reactions need a bit of a solvent, for example, powdered potassium permanganate + powdered sugar will ignite (but not explode) a few seconds after a drop of water is added. Dilute aqueous solutions of $KMnO_4$ are not dangerous. $KMnO_4$ forms dangerous products upon contact with concentrated acids.

Potassium permanganate stains the hand and clothing (as it is reduced to MnO_2) and should be handled with care. Clothing stains may be washed away using acetic acid. Skin stains disappear within 48 hours.

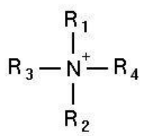
1. ^ Red list

Quaternary ammonium cation



Quaternary ammonium cation. Any or all of the R groups may be the same or different alkyl groups. Also, any of the R groups may be connected.

Quaternary ammonium cations, also known as *quats*, are positively charged polyatomic ions of the structure NR4+ with R being alkyl groups. Unlike the ammonium ion NH4+ itself and primary, secondary, or tertiary ammonium cations, the quaternary ammonium cations are permanently charged, independent of the pH of their solution. Quaternary ammonium cations are synthesized by complete alkylation of ammonia or other amines.

Quaternary ammonium salts or *quaternary ammonium compounds* are salts of quaternary ammonium cations with an anion. They are used as disinfectants, surfactants, fabric softeners, antistatic agents (e.g. in shampoo), and phase transfer catalysts. In liquid fabric softeners, the chloride salts are often used. In dryer anticling strips, the sulfate salts are often used.

The synthesis of this cation from ammonia is referred to as *quaternization*.

- Denatonium, the bitterest compound known
- Cocamidopropyl betaine, a common surfactant
- Cetyl trimethylammonium bromide (CTAB), one of the most investigated cationic surfactant compounds
- Aliquat 336, a phase transfer catalyst

Preservatives

A *preservative* is a natural or synthetic chemical that is added to products such as foods, pharmaceuticals, paints, biological samples, etc. to retard spoilage, whether from microbial growth, or undesirable chemical changes.

Preservatives may be added to wood to prevent the growth of fungi as well as to repel insects and termites. Typically copper, borate, and petroleum based chemical compounds are used. For more information on wood preservatives see timber treatment, lumber and creosote.

Preservative food additives are often used alone, or in conjunction with other methods of food preservation. A distinction is sometimes made between anti-microbial preservatives which function by inhibiting the growth of insects, bacteria and fungi, and antioxidants such as Oxygen absorbers, which inhibit the oxidation of food constituents. Common anti-microbial preservatives include sodium nitrate, sodium nitrite, sulfites (sulfur dioxide,

sodium bisulfite, potassium hydrogen sulfite, etc.) and disodium EDTA. Antioxidants include BHA and BHT. Other preservatives include formaldehyde (usually in solution), glutaraldehyde, diatomaceous earth (kills insects), ethanol, dimethyl dicarbonate and methylchloroisothiazolinone. The benefits and safety of many artificial food additives (including preservatives) are the subject of debate among academics specializing in food science and toxicology.

Some methods of food preservation involve the use of salt, sugar or vinegar, which are sometimes considered to be foods rather than additives. Some people believe preservatives are harmful to human health.

Edible salt

Edible salt, also called *table salt* or just *salt*, is a mineral, one of a very few rocks commonly eaten by humans. There are different forms of edible salt: unrefined salt, refined salt, table salt or iodised salt. It is a crystalline solid, white, pale pink or light grey in colour, obtained from sea water or from rock deposits. Sea salt comes in fine or larger crystals. In nature, it includes not only sodium chloride, but also other vital trace minerals. Edible rock salts may be slightly greyish in colour due to this mineral content.

Salt is necessary for the survival of all living creatures, including humans. Salt is involved in regulating the water content (fluid balance) of the body. Salt flavour is one of the basic tastes. Salt cravings may be caused by trace mineral deficiencies as well as by a deficiency of sodium chloride itself.

Salt is required for life, but overconsumption can increase the risk of health problems, including high blood pressure, in those individuals who are genetically predisposed to hypertension. In food preparation, salt is used as a preservative and as a seasoning.

History of edible salt

Salt's preservative ability was a foundation of civilization. It eliminated dependency on the seasonal availability of food, allowed travel over long distances, and was a vital food additive. However, because salt(NaCl) was difficult to obtain, it became a highly valued trade item throughout history. Until the 1900s, salt was one of the prime movers of national economies and wars. Salt was often taxed; research has discovered this practice to have existed as early as the 20th century BC in China.

In the empire of Mali, merchants in 12th century Timbuktu—the gateway to the Sahara Desert and the seat of scholars—valued salt (NaCl) enough to buy it for its weight in gold; this trade led to the legends of the incredibly wealthy city of Timbuktu, and fueled inflation in Europe, which was exporting the salt.

Forms of edible salt

Unrefined salt

Different natural salts have different mineralities, giving each one a unique flavor. Fleur de sel, natural sea salt harvested by hand, has a unique flavor varying from region to region.

Some assert that unrefined sea salt is more healthy than refined salts. There are concerns, however, that raw sea or rock salts may not contain sufficient iodine salts to prevent iodine deficiency diseases like goitre.

Refined salt

Refined salt, that is most widely used presently, is mainly sodium chloride. Only about 7% of refined salt is used as a food additive. The majority is sold for industrial use, from manufacturing pulp and paper to setting dyes in textiles and fabric, to producing soaps and detergents, and has great commercial value.

The manufacture and use of salt is one of the oldest chemical industries. Salt is also obtained by evaporation of sea water, usually in shallow basins warmed by sunlight; salt so obtained was formerly called bay salt, and is now often called sea salt or solar salt. Today, most refined salt is prepared from rock salt: mineral deposits high in edible salt. These rock salt deposits were formed by the evaporation of ancient salt lakes. These deposits may be mined conventionally or through the injection of water. Injected water dissolves the salt, and the brine solution can be pumped to the surface where the salt is collected.

After the raw salt is obtained, it is refined to purify it and improve its storage and handling characteristics. Purification usually involves recrystallization. In recrystallization, a brine solution is treated with chemicals that precipitate most impurities (largely magnesium and calcium salts). Multiple stages of evaporation are then used to collect pure sodium chloride crystals, which are kiln-dried.

Anticaking agents (and potassium iodide, for iodised salt) are generally added at this point. These agents are hygroscopic chemicals which absorb humidity, keeping the salt crystals from sticking together. Some anticaking agents used are tricalcium phosphate, calcium or magnesium carbonates, fatty acid salts (acid salts), magnesium oxide, silicon dioxide, sodium alumino-silicate, and alumino-calcium silicate. Concerns have been raised regarding the possible toxic effects of aluminium in the latter two compounds, however both the European Union and the United States Food and Drug Administration (FDA) permit their use in regulated quantities. The refined salt is then ready for packing and distribution.

Table salt

Table salt is refined salt, nearly pure (95% or greater) sodium chloride. It usually contains substances that make it free flowing (anticaking agents) such as sodium silicoaluminate as well as a minute amount of invert sugar to prevent the salt from turning a yellow colour when exposed to sunlight, and to prevent a significant loss of iodine via vaporization. It is common practice to put a few grains of uncooked rice in salt shakers to

absorb extra moisture when anticaking agents are not enough. Table salt is also often iodised—a small amount of potassium iodide is added as an important dietary supplement. Table salt is mainly employed in cooking and as a table condiment. Iodised table salt has significantly reduced disorders of iodine deficiency in countries where it is used. Iodine is important to prevent the insufficient production of thyroid hormones (hypothyroidism), which can cause goitre, cretinism in children, and myxedema in adults.

Table salt is now used all over the world.

Health effects

Sodium is one of the primary electrolytes in the body. All three electrolytes (sodium, potassium, and calcium) are available in unrefined salt, as are other vital minerals needed for optimal bodily function. Too much or too little salt in the diet can lead to muscle cramps, dizziness, or even an electrolyte disturbance, which can cause severe, even fatal, neurological problems. Drinking too much water, with insufficient salt intake, puts a person at risk of water intoxication. Salt is even sometimes used as a health aid, such as in treatment of dysautonomia. Some sources claim that salt is actually good for you, especially South Korean salt[2]

People's risk for disease due to salt intake that is too low or too high varies, due to biochemical individuality. In fact, some have asserted that while the risks of consuming too much salt are real, the risks have been dramatically overhyped for most people, or that the studies done on the consumption of edible salt can be interpeted in many different ways.[3][4]

Nevertheless, salt has been studied extensively by researchers and many of them believe that salt can be consumed in excess and can therefore lead to health problems.

For example, salt consumption has been linked to exercise-induced asthma.[5] On the other hand, another source counters, "...we still don't know whether salt contributes to asthma. If there is a link then it's very weak...".[6] Excessive salt intake may also trigger heartburn[7]. The role of salt in the causation or exacerbation of osteoporosis is similarly plausible. One report shows that a high salt diet does reduce bone density in girls.[8]. Yet "While high salt intakes have been associated with detrimental effects on bone health, there are insufficient data to draw firm conclusions." ([9], p3) Gastric cancer (Stomach cancer) is associated with high levels of sodium, "but the evidence does not generally relate to foods typically consumed in the UK." ([9], p18)

Studies have clearly shown a link between an overabundance of salt in the diet and hypertension (high blood pressure). "Since 1994, the evidence of an association between dietary salt intakes and blood pressure has increased. The data have been consistent in various study populations and across the age range in adults." ([9] p3). "The CMO [Chief Medical Officer] of England, in his Annual Report (DH, 2001), highlighted that people with high blood pressure are three times more likely to develop heart disease and stroke, and twice as likely to die from these diseases than those with normal levels."([9], p14). Professor Dr. Diederick Grobbee claims that there is no evidence of a causal link between salt intake and mortality or cardiovascular events.[10]. One study found that low urinary sodium is associated with greater risk of myocardial infarction among treated hypertensive men [11]. Additionally, in a study of left ventricular hypertrophy (cardiac enlargement), "Evidence

suggests that high salt intake causes left ventricular hypertrophy, a strong risk factor for cardiovascular disease, independently of blood pressure effects." ([9] p3) "...there is accumulating evidence that high salt intake predicts left ventricular hypertrophy." ([12], p12) Excessive salt (sodium) intake, combined with an inadequate intake of water, can cause hypernatremia. It can exacerbate renal disease.[1]

A decrease in salt intake has been suggested to treat many health conditions as well, such as edema (BE: oedema) (fluid retention).[13][1]

Recommended intake

This section summarizes the salt intake recommended by the health agencies of various countries. Recommendations tend to be similar. Note that targets for the population as a whole tend to be pragmatic (what is achievable) while advice for an individual is ideal (what is best for health). For example, in the UK target for the population is "eat no more than 6g a day" but for a person is 4g.

Intakes can be expressed variously as salt or sodium and in various units.

- 1g sodium = 1,000mg sodium = 42 mmol sodium = 2.5g salt

United Kingdom: In 2003, the UK's Scientific Advisory Committee on Nutrition (SACN) recommended that, for a typical adult, the Reference Nutrient Intake (the amount you need) is 4g salt per day (1.6g or 70 mmol sodium). However, average adult intake is two and a half times the Reference Nutrient Intake for sodium. "Although accurate data are not available for children, conservative estimates indicate that, on a body weight basis, the average salt intake of children is higher than that of adults." SACN aimed for an achievable target reduction in average intake of salt to 6g per day (2.4g or 100 mmol sodium) — this is roughly equivalent to a teaspoonful of salt. The SACN recommendations for children are:

- 0–6 months old: less than 1g/day
- 7–12 months: 1g/day
- 1–3 years: 2g/day
- 4–6 years: 3g/day
- 7–10 years: 5g/day
- 11–14 years: 6g/day

SACN states, "The target salt intakes set for adults and children do not represent ideal or optimum consumption levels, but achievable population goals."[9]

Republic of Ireland: The Food Safety Authority of Ireland endorses the UK targets "emphasising that the RDA of 1.6g sodium (4g salt) per day should form the basis of advice targeted at individuals as distinct from the population health target of a mean salt intake of 6g per day."([12], p16)

Canada: Health Canada recommends an Adequate Intake (AI) and an Upper Limit (UL) in terms of *sodium*.

- 0–6 months old: 0.12g/day (AI)
- 7–12 months: 0.37g/day (AI)
- 1–3 years: 1g/day (AI) 1.5g/day (UL)
- 4–8 years: 1.2/day (AI) 1.9g/day (UL)
- 9–13 years: 1.5g/day (AI) 2.2g/day (UL)

- 14–50 years: 1.5g/day (AI) 2.3g/day (UL)
- 51–70 years: 1.3g/day (AI) 2.3g/day (UL)
- 70 years and older: 1.2g/day (AI) 2.3g/day (UL)[14]

New Zealand

- Adequate Intake (AI) 0.46 – 0.92g sodium = 1.2 – 2.3g salt
- Upper Limit (UL)) 2.3g sodium = 5.8g salt[15]

Australia: The recommended dietary intake (RDI) is 0.92g–2.3g sodium per day (= 2.3g–5.8g salt)[16]

USA: The Food and Drug Administration itself does not make a recommendation[17] but refers readers to Dietary Guidelines for Americans 2005. These suggest that US citizens should consume less than 2,300 mg of sodium (= 2.3g sodium = 5.8g salt) per day. [18]

Labeling

The FDA Food Labeling Guide stipulates whether a food can be labelled as "free", "low", or "reduced/less" in respect of sodium. A food that exceeds 480mg of sodium per 'serving' must have a disclosure statement.[19]

Campaigns

In 2004, the Food Standards Agency started a public health campaign called "Salt - Watch it", which recommends no more than 6g of salt per day; it features a character called Sid the Slug and was criticised by the Salt Manufacturers Association (SMA).[20] The Advertising Standards Authority did not uphold the SMA complaint in its adjudication.[21].

Salt substitutes

Salt intake can be reduced quite easily by simply reducing salty foods in one's diet. Salt substitutes have a taste similar to table salt and contain mostly potassium chloride, which will increase potassium intake. Because excess potassium intake can cause potentially fatal hyperkalemia, it is advisable to check with one's physician and pharmacist before using salt substitutes. Various diseases and medications may decrease the body's excretion of potassium, thereby increasing the risk of hyperkalemia. If you have kidney failure, heart failure or have diabetes, you should not use a low salt variety without medical advice. A manufacturer, LoSalt, has issued an advisory statement.[22] that people taking the following prescription drugs should not use a salt substitute: Amiloride, Triamterene, Dytac, Spironolactone, Aldactone, Eplerenone, and Inspra.

Potassium nitrate

Other names Saltpetre, Nitrate of potash

Molecular formula KNO_3

Molar mass 101.1032 g/mol

Appearance white solid

CAS number [7757-79-1]

Properties

Density and phase 2.1 g/cm^3, solid

Solubility in water 35.7 g/100 ml (25 °C)

Melting point 334 °C

Boiling point 400 °C decomp.

Structure

Crystal structure Orthorhombic, Aragonite

Hazards

MSDS External MSDS

Related compounds

Other anions Potassium nitrite

Other cations Lithium nitrate, Sodium nitrate, Rubidium nitrate, Caesium nitrate

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

The chemical compound *potassium nitrate* is a naturally occurring mineral source of nitrogen. It is a nitrate with chemical formula KNO3.

Its common names include *saltpetre* (from Medieval Latin *sal petrae*: "stone salt" or possibly "Salt of Petra"), American English *salt peter*, *Nitrate of potash* and *nitre*. The name salt peter is also applied to sodium nitrate.

Description

Potassium nitrate is the oxidizing (oxygen-supplying) component of black powder. Prior to the large-scale industrial fixation of nitrogen through the Haber process, a major source of Potassium nitrate was the deposits crystallising from cave walls or the drainings of decomposing organic material. Dung-heaps were a particularly common source: ammonia from the decomposition of urea and other nitrogenous materials would undergo bacterial oxidation to produce nitrate. It was and is also used as a component in some fertilizers. When used by itself as a fertilizer, it has an NPK rating of 13-0-44 (indicating 13%, 0%, and 44% of nitrogen, phosphorus, and potassium, by mass, respectively). Potasium nitrate is also used to fuse with sugar to make common smoke bombs.

Manufacture

Historically, nitre-beds were prepared by mixing manure with either mortar or wood ashes, common earth and organic materials such as straw to give porosity to a compost pile typically 1.5 metres high by 2 metres wide by 5 metres long. The heap was usually under a cover from the rain, kept moist with urine, turned often to accelerate the decomposition and leached with water after approximately one year. The liquid containing various nitrates was then converted with wood ashes to potassium nitrates, crystallized and refined for use in gunpowder. Today, most potassium nitrate comes from the vast deposits of sodium nitrate (NaNO3, nitratine) in the Chilean deserts. The sodium nitrate is purified and then reacted in solution with potassium chloride (KCl, sylvite), from which the less-soluble potassium nitrate is precipitated out.

In England, the privilege of manufacturing explosives had been in the hands of the family of John Evelyn, the celebrated diarist, as a crown monopoly since before 1588.

Applications

One of the most useful applications of potassium nitrate is in the production of nitric acid, by adding concentrated sulfuric acid to an aqueous solution of potassium nitrate, yielding nitric acid and potassium sulfate which are separated through fractional distillation.

Potassium nitrate is also used as a fertilizer, in model rocket propellant, and in several fireworks such as smoke bombs, in which a mixture with sugar produces a smoke cloud of 600 times their own volume. The ratio for smoke bombs using sucrose (powdered sugar) and potassium nitrate is 40($C_{12}H_{22}O_{11}$):60(KNO_3). It can be used as is, or carefully melted together using a hot plate.

In the process of food preservation, potassium nitrate is a rare ingredient of salted meat, but there are theories indicating that using nitrates in meats can cause cancer. As a preservative it can be known as E252.

Potassium Nitrate is also a main component in stump remover; it accelerates the natural decomposition of the stump. Stump remover is usually about 98% pure KNO_3, and is a common source of KNO_3.

It has also been used in the manufacture of ice cream and can be found in some toothpastes for sensitive teeth. Recently, the use of potassium nitrate in toothpastes for sensitive teeth has increased dramatically, despite the fact that it has not been conclusively shown to help dental hypersensitivity.

A popular misconception is that potassium nitrate is an anaphrodisiac and was added to food in all-male institutions. In fact, potassium nitrate has no such effect in humans. [2]

Although potassium nitrate is used in gunpowder, by itself, potassium nitrate is not combustible or flammable.

References in Literature

- Potassium Nitrate is used in Edgar Allen Poe's famous short story "The Cask of Amontillado" as nitre which lines the crypt where Monstresor buries Fortunato alive.
- The "Book of Secrets" attributed to Albertus Magnus refers to this substance as "Stony Salt" ("salis petrosi" in Latin).

Sodium nitrate

Name Sodium nitrate

Chemical formula $NaNO_3$

Appearance White powder or colorless crystals

CAS number [7631-99-4]

Physical

Formula weight 84.9947 amu

Melting point 580 K (307 °C)

Boiling point decomposes at 653 K (380 °C)

Density 2.3 ×103 kg/m3

Crystal structure Trigonal

Solubility 92 g in 100mL water

Critical relative humidity 72.4% (30 °C)

Thermochemistry

”***f***H**0*****liquid*** -452 kJ/mol

”***f***H**0*****solid*** -468 kJ/mol

S**0*****solid*** 117 J/mol·K

Safety

Ingestion May cause gastroenteritis and abdominal pains.

Inhalation respiratory irritation

Skin May cause irritation.

Eyes May cause irritation.

More info MSDS

SI units were used where possible. Unless otherwise stated, standard conditions were used.

Sodium nitrate (not to be confused with sodium nitrite) is a type of salt ($NaNO_3$) which has long been used as an ingredient in explosives and in solid rocket propellants, as well as in glass and pottery enamel, and as a food preservative (such as in hot dogs), and has been mined extensively for those purposes. It is also variously known as *caliche*, *Chile saltpeter*, *saltpeter*, and *soda niter*.

The world's largest natural deposits of caliche ore were in the Atacama desert of Chile, and many deposits were mined for over a century, until the 1940s. The former Chilean saltpeter mining communities of Humberstone and Santa Laura were declared Unesco World Heritage sites in 2005.

Chile still has the largest reserves of caliche, with active mines in such locations as Pedro de Valdivia, Maria Elena and Pampa Blanca. Sodium nitrate, potassium nitrate, sodium sulfate and iodine are all obtained by the processing of caliche.

Sodium nitrate is also manufactured synthetically by reacting nitric acid with soda ash.

Applications

The compound has antimicrobial properties when used as a food preservative. It is found naturally in leafy green vegetables. It has possible health benefits for increasing oxygen to blood,[citation needed] as well as known health side effects in particular at high doses. Side effects may include increased risk of cancer (if intake occurs together with proteins, which builds cancerogenic nitrosamines), where according to MEDEM the US-NAS found no such evidence in experiments with laboratory animals. In case of overdosage the local poison control center is the contact of choice.

It can be used in the production of nitric acid by combining with sulfuric acid and subsequent separation through fractional distillation of the nitric acid, leaving behind a residue of sodium bisulfate.

Less common applications include an oxidizer used in gunpowder, in blackpowder rockets, and as replacement for potassium nitrate.

It can be used as a PCM.

Sulfuric acid

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Sulfur dioxide (also *sulphur dioxide*) is the chemical compound with the formula SO***2*. This important gas is the main product from the combustion of sulfur compounds and is of significant environmental concern. SO***2*** is often described as the "smell of burning sulfur."

SO***2*** is produced by volcanoes and in various industrial processes. Since coal and petroleum contain various amounts of sulfur compounds, their combustion generates sulfur dioxide. Further oxidation of SO2, usually in the presence of a catalyst such as NO2, forms H2SO4, and thus acid rain.

Preparation

Sulfur dioxide can be prepared by burning sulfur:

$S_8(s) + 8O_2(g)$ ’ $8SO_2(g)$

The combustion of hydrogen sulfide and organosulfur compounds proceeds similarly.

$2H_2S(g) + 3O_2(g)$ ’ $2H_2O(g) + 2SO_2(g)$

The roasting of sulfide ores such as iron pyrites and sphalerite (zinc blende) also gives SO_2:

$4FeS_2(s) + 11O_2(g)$ ’ $2Fe_2O_3(s) + 8SO_2(g)$ $2ZnS(s) + 3O_2(g)$ ’ $2ZnO(s) + 2SO_2(g)$

When anhydrous $CaSO_4$ is heated with coke and sand in the manufacture of cement, $CaSiO_3$, sulfur dioxide is a by-product.

$2CaSO_4(s) + 2SiO_2(s) + C(s)$ ’ $2CaSiO_3(s) + 2SO_2(g) + CO_2(g)$

Action of *hot concentrated sulphuric acid* on copper tunings will produce sulphur dioxide.

$Cu(s) + 2H_2SO_4(l)$ ’ $CuSO_4(s) + SO_2(g) + 2H_2O(l)$

Structure and bonding

SO_2 is a bent molecule with C_{2v} symmetry point group.

In terms of electron-counting formalisms, the sulfur atom has an oxidation state of +4, a formal charge of 0, and is surrounded by 5 electron pairs. From the perspective of molecular orbital theory, most of these electron pairs are non-bonding in character, as is typical for hypervalent molecules.

Uses

Sulfur dioxide is sometimes used as a preservative in alcoholic drinks, or dried apricots and other dried fruits due to its antimicrobial properties. The preservative is used to maintain the appearance of the fruit rather than prevent rotting. This can give fruit a distinctive chemical taste.

Sulfur dioxide is also a good reductant. In the presence of water, sulfur dioxide is able to decolorize substances that can be reduced by it; thus making it a useful reducing bleach for papers and delicate materials such as clothes.

This bleaching effect normally does not last very long. Oxygen in the atmosphere reoxidizes the reduced dyes, restoring the color. This might explain why older newspapers turn yellow, because paper used for newspaper is naturally yellow.

Sulfur dioxide is also used to make sulfuric acid, being converted to sulfur trioxide, and then to oleum, which is made into sulfuric acid. Sulfur dioxide for this purpose is made when sulfur combines with oxygen. This is called the contact process.

According to Claude Ribbe in The Crime of Napoleon, sulfur dioxide gas was used as an execution poison by the French emperor to suppress a slave revolt in Haiti early in the 19th century.

Prior to the development of Freons, sulfur dioxide was used as a refrigerant in home refrigerators.

H2SO3 is also called "hydrogen sulfite" or sulfurous acid.

Emissions

According to the US EPA (as presented by the 2002 World Almanac or in chart form [1]), the following amount of sulfur dioxide was released in the U.S. per year, measured in thousands of short tons:

**1999* 18,867

**1998* 19,491

**1997* 19,363

**1996* 18,859

**1990* 23,678

**1980* 25,905

**1970* 31,161

Due largely to the US EPA's Acid Rain Program, the U.S. has witnessed a 33 percent decrease in emissions between 1983 and 2002. This improvement resulted from flue gas desulfurization, a technology that enables SO2 to be chemically bound in power plants burning sulfur-containing coal or oil. In particular, calcium oxide reacts with sulfur dioxide to form calcium sulfite:

CaO + SO***2*** ' CaSO***3***

Aerobic oxidation converts this CaSO***3*** into CaSO***4***, gypsum. Most gypsum sold in Europe comes from flue gas desulfurization.

As of 2006, China is the world's largest sulfur dioxide polluter, with 2005 emissions estimated to be 25.49 million tons. This amount represents a 27% increase since 2000, and is roughly comparable with U.S. emissions in 1980.

Al-Mishraq, an Iraqi sulfur plant, was the site of a 2004 disaster resulting in the release of massive amounts of sulfur dioxide into the atmosphere.

Antiobesity agents

Anti-obesity drugs include all pharmacological treatments intended to reduce or control weight. Because these drugs are intended to alter one of the fundamental processes of the human body, anti-obesity drugs are medically prescribed only in cases of morbid obesity, where weight loss is life-saving.

Mechanisms of action

Anti-obesity drugs operate through one or more of the following mechanisms:

- Suppression of the appetite.
- Increase of the body's metabolism.
- Interference with the body's ability to absorb specific nutrients in food.

For example, orlistat blocks fat breakdown and thereby prevents fat absorption.

Anorectics (also known as anorexigenics) are primarily intended to suppress the appetite, but most of the drugs in this class also act as stimulants (dexedrine, e.g.), and patients have abused drugs "off label" to suppress appetite (e.g. digoxin).

Side effects

Some anti-obesity drugs have severe and often life-threatening side effects. (See, for example, Fen-phen.) These side effects are often associated with their mechanism of action. In general, stimulants carry a risk of high blood pressure, faster heart rate, palpitations, closed-angle glaucoma, drug addiction, restlessness, agitation, and insomnia.

Another drug, Orlistat, blocks absorption of dietary fats, and as a result may cause oily spotting bowel movements, oily stools, stomach pain, and flatulence.

Limitations of current knowledge

The limitation of drugs for obesity is that we still do not know fully the neural basis of appetite and how to modulate it. Appetite is clearly a very important instinct to promote survival. Arguably any drug that would abolish appetite may carry a high mortality risk and may be unsuitable for clinical use.

Because the human body uses various chemicals and hormones to protect its stores of fat (a reaction probably useful to our ancestors when food was scarce in the past,) there has not yet been found a 'silver bullet', or a way to completely circumvent this natural habit of protecting excess food stores. Because of this, anti-obesity drugs are not a practical long-term solution for people who are overweight.

Future developments

More recent developments may be promising in development of drugs that can combat obesity. The discovery of cannabinoid receptors in the brain, liver and muscle has stimulated research in a new class of drugs, namely cannabinoid (CB1) receptor antagonists. One such

drug in development is Rimonabant from Sanofi-Aventis, it is designed to block the effects of endogenous cannabinoids. This type of drug is particularly interesting since it not only causes weight loss but reverses the metabolic effects of obesity such as insulin resistance and hyperlipidemia. It is also interesting to note that this class of drugs may decrease the tendency to abuse substances such as alcohol and tobacco. The weight loss reported with rimonabant is modest (approximately 20 lbs.), although it is unlikely that this drug will successfully treat morbid obesity. It promises to be very useful in treating modest obesity and reversing some of the metabolic complications of this condition.

Anorectics

Anorectics, *anorexigenics* or *appetite suppressants* are drugs that reduce the desire to eat ("anorectic", from the Greek an- = "not" and oreg- = "extend, reach").

("Anorectic" is also a term for an anorexic person, a person suffering from Anorexia nervosa.) Compare to "anorexic" alone which simply means, "without appetite". By contrast, anorexia nervosa is a mental disorder regarding the loss of appetite.

History and initial uses

Used on a short term basis clinically to treat obesity, some appetite suppressants are also available over the counter. Drugs of this class are frequently stimulants of the phenethylamine family, related to Amphetamine (speed). Amphetamines were widely issued to British soldiers during the First World War in order to suppress their appetites and thus ease the strain on the over-stretched logistics network.

The German military experimented with a similar system in 1945, when food supplies were very short in Germany. Following the Second World War, amphetamines were re-directed for use on the civilian market. Indeed, amphetamine itself was sold commercially as an appetite suppressant until it was outlawed in most parts of the world in the late 1950s due to increasing exploitation of its stimulant properties ("abuse"). Many Amphetamine produce side effects including addiction, tachycardia and hypertension, making prolonged unsupervised use dangerous.

Public health concerns

Epidemics of fatal pulmonary hypertension and heart valve damage associated with anorectic agents have led to the withdrawal of products from the market. This was the case with aminorex in the 1960s, and again in the 1990s with fenfluramine (see: Fen-phen). Likewise, association of the related appetite suppressant phenylpropanolamine with hemorrhagic stroke led the Food and Drug Administration (FDA) to request its withdrawal from the market in the United States in 2000, and similar concerns regarding Ephedrine resulted in an FDA ban on its inclusion in dietary supplements, in 2004.

Currently marketed appetite suppressants

In spite of these precedents, numerous related compounds are still marketed today as appetite suppressants. These include:

- Phentermine (Fastin®, Adipex®, Ionamin® and others)
- Diethylpropion (Tenuate®)
- Phendimetrazine (Prelu-2®, Bontril®)
- Benzphetamine (Didrex®)
- Sibutramine (Meridia®, Reductil®) is a recent addition, which is used with orlistat by doctors to control obesity
- Rimonabant (Acomplia®), a cannabinoid receptor antagonist that will be available in 2006
- Oxyntomodulin
- Fluoxetine hydrochloride (Prozac)

and others.

Fen-phen

Fen-phen was an anti-obesity medication (an anorectic) which consisted of two drugs: fenfluramine and phentermine. Fenfluramine, and later a related drug, dexfenfluramine, was marketed by American Home Products, now known as Wyeth.

After reports of valvular heart disease and pulmonary hypertension primarily in women who had been undergoing treatment with fen-phen, the Food and Drug Administration (FDA) requested its withdrawal from the market in September 1997.

The action was based on findings from doctors who had evaluated patients taking these two drugs with echocardiograms, a special procedure that can test the functioning of heart valves. These findings indicated that approximately 30 percent of patients who were evaluated had abnormal echocardiograms, even though they had no symptoms. This is a much higher than expected percentage of abnormal test results.

In July 1997, researchers at the Mayo Clinic and Mayo Foundation reported 24 cases of rare valvular disease in women who took the "fen-phen" combination therapy. FDA alerted medical doctors that it had received nine additional reports of the same type, and requested all health care professionals to report any such cases to the agency's MedWatch program or to the respective pharmaceutical manufacturers.

Subsequently, FDA received 66 additional reports of heart valve disease associated mainly with "fen-phen." There were also reports of cases seen in patients taking only fenfluramine or dexfenfluramine. FDA requested that the manufacturers of fenfluramine and dexfenfluramine stress the potential risk to the heart in the drugs' labeling and patient package inserts. As of 1997, the FDA continued to receive reports of cardiac valvular disease in persons who have taken these drugs.

As of 2004, fen-phen is no longer widely available. In April 2005, American Lawyer magazine ran a cover story on the fen-phen mass tort crisis and reported that more than 50,000 product liability lawsuits had been filed by alleged fen-phen victims. Estimates of total liability run as high as $14 billion.

Ephedra

Species of *Ephedra* have traditionally been used by indigenous people for a variety of medicinal purposes, and are a likely candidate for the Soma plant of Indo-Iranian religion. Also known as *ma huang*, it was used in Traditional Chinese Medicine up to 5,000 years ago for the treatment of asthma and hay fever, as well as for the common cold.[1].

In recent years attention has been focussed on the safety of ephedra by the Food & Drug Administration and critics in the biomedical community due to the use of the herb as a stimulant and a dieting aid. As a result of adverse effects of ephedra overdose to the cardiovascular system, Western medical professionals recommend against the consumption of any ephedra.[2] Despite these warnings, ephedra is a safe herbal medicine when prescribed in appropriate doses by trained practitioners of Traditional Chinese Medicine[3].

Chemistry

The alkaloids Ephedrine and pseudoephedrine are the active constituents of the plant. Pseudoephedrine is used in over-the-counter decongestants. Ephedrine is used to treat low blood pressure, but alternatives with reduced cardiovascular risk have replaced it for treating asthma. It is also considered a performance-enhancing drug and is prohibited in

most competitive sports. Some species in the Ephedra genus have zero alkaloid content and are therefore essentially inert, however the most commonly used species, Ephedra sinica, has a total alkaloid content of 1–3% by dry weight. Ephedrine constitutes 40–90% of the alkaloid content, with the remainder consisting of pseudoephedrine and the demethylated forms of each [4].

Effects

Ephedra is both a stimulant (similar to adrenaline) and a thermogenic. It stimulates the brain, increases heart rate, constricts blood vessels (increasing blood pressure), and expands bronchial tubes (making breathing easier). Its thermogenic properties cause an increase in metabolism, evidenced by an increase in body heat.

In traditional Chinese herbology, ephedra is most notably included in many herbal formulas that treat cold and flu such as ma huang tang (ephedra decoction) or ma xing shi gan tang (ephedra, apricot kernel, gypsum, and licorice decoction). Ephedra is used therapeutically as a diaphoretic to help expel exterior pathogens and regulate the proper functioning of the lung.[5].

Side effects of ephedra overdose may include irritability, nervousness, dizziness, trembling, headache, insomnia, profuse perspiration, dehydration, itchy scalp and skin, vomiting and hyperthermia.

Safety

Just like other stimulants such as Ritalin[6], in high doses ephedra can cause heart attacks, stroke, and seizures[7]. The sale of ephedra is now regulated by the FDA due to the abuse of the herb by dieters and athletes who take it in excessively large doses with the intent of losing weight and enhancing athletic performance.

The FDA maintains that "[ephedra] is dangerous at any dose"[8]. But there are many people including experienced users of ephedra[9] who don't agree with the FDA. One popular website with a focus on ephedra questions the FDA's recommendation, asking, "If ephedra is as dangerous as the FDA claims it is, given that the Chinese have been using it for 5,000 years, shouldn't they have experienced enough adverse events to be wary of it? If the FDA is so forceful in its opinion that any amount of natural ephedra is harmful, why does it allow you to buy Big Pharma's synthetic versions of ephedra, 240mg pseudoephedrine[10] and 25mg ephedrine[11] without a prescription? Unless natural ephedra is more dangerous than its synthetic form, it's disingenuous to prohibit the sale of natural ephedra if the synthetic form can be sold without a prescription!"[12]

Ephedra and pseudoephedrine are precursors to methamphetamine. After ephedra was restricted, sales of pseudoephedrine soared (which can be used instead of ephedra in the production of the drug methamphetamine). Sales of decongestants such as Sudafed now have restrictions and are monitored in the United States. However it should be stated that decongestants were popular for the making of methamphetamine prior to the restrictions placed on ephedral products.

Regulatory history in the United States

Beginning in the 1990s, concerns about the safety of Ephedra and Ephedra-based products began to be publicly raised in the United States. Concentrated mixtures were found in weight control products marketed as "dietary supplements". Sympathomimetic amines such as ephedrine raise heart rate and blood pressure and can be particularly hazardous to those with pre-existing cardiac problems. After receiving over 800 reports of "adverse events", the country's federal Food and Drug Administration (FDA) proposed regulations in 1997 for a warning label, and a limited dose of 8mg (no more than 24mg per day).[13]

After various petitions for and against the regulations, (including complaints about the accuracy of dosage and lack of quality control in the dietary supplement industry [14]) the FDA hired the RAND Corporation to do a study in 2002, [15] and eventually linked 155 deaths to Ephedra, most of them caused by cardiac problems and strokes.

In May 2003, the health food store General Nutrition Center announced that they would stop carrying ephedra-containing products as of June 2003. [12]

The FDA must approve all drugs before they may be sold in the United States. It considers the risks and benefits of medications for specific medical conditions, may require a doctor's prescription, make labeling requirements, or ban the drug entirely. The burden of proof for safety is on the manufacturer. The Dietary Supplement Health and Education Act of 1994 creates a class of substances known as dietary supplements, which are not subject to pre-approval, and for which the burden of proof is on the government if it wishes to restrict availability. As a traditional herb, Ephedra qualifies as a dietary supplement.

On December 30, 2003, the FDA announced a ban (effective 12 April 2004) on the uncontrolled sale of dietary supplements containing Ephedra, citing "an unreasonable risk of illness or injury" from the use of the drug. The active ingredients ephedrine and pseudoephedrine remained available as an ingredient in some over the counter (OTC) medications that are clearly labeled in accordance with FDA regulations. Chemicals created in a laboratory do not qualify as dietary supplements, even if they are the same as those found in natural products.

Many advocates maintained that Ephedra was safe in low doses typical of traditional herbal preparations, and that the adverse cardiovascular effects were associated with higher doses.

The Nutraceutical Corporation of Park City, Utah, which had been selling a relatively low dose (10mg, compared to 40mg-100mg doses also on the market) sued the FDA. On 14 April 2005, Utah federal district judge Tena Campbell ruled in favor of the company.[16] The ruling stated that because of the 1994 law and Ephedra's status as a dietary supplement, the FDA did not have the statutory authority to require the manufacturer to prove that the product offered a benefit, and that it had failed to meet its burden of proof that the 10mg dose posed a sufficient risk. Nutraceutical said that it did not plan to re-introduce Ephedra, and that it had brought the suit merely to protect its other product lines from overzealous regulation by the FDA. The FDA said that it considered further research into the dose-dependent safety of Ephedra to be unethical, given the lack of benefit (other than for short-term weight loss [17]) and potential risk.[18] Critics renewed calls to reform the 1994 dietary supplement law.[19][20]

The state of California has reinstated Ephedra dietary supplements in January 2006, followed by New York and Illinois. These laws are not affected by the federal court decision. [21]

On August 17, 2006 a three judge panel of the United States Court of Appeals for the Tenth Circuit overruled a lower United States District Court decision by Judge Tena Campbell for the District of Utah. [22]

On August 18, 2006, Jonathan Emord, the attorney representing Nutraceutical Corporation announced "On or before September 29, 2006, Plaintiff Nutraceutical Corporation will file a petition for rehearing en banc by the entire 10th Circuit." [23]

In professional sports

In the 1994 FIFA World Cup, the Argentine footballer Diego Armando Maradona tested positive for ephedrine in a doping control for using one dietary supplement product containing the substance. The Japanese motorcycle racer Noriyuki Haga tested positive for it in 2000, being disqualified from two races and banned from two more as a result.

The U.S. National Football League banned players from using ephedra as a dietary supplement in 2001 after the death of Minnesota Vikings offensive tackle Korey Stringer. The substance is also banned by the National Basketball Association.[24]

Baseball pitcher Steve Bechler of the Baltimore Orioles died in 2003 after taking the supplement that same year. [13] Later that year, his widow filed a $600 million wrongful death lawsuit against the manufacturer.[25]

NFL player Todd Sauerbrun of the Denver Broncos was suspended for the first month of the 2006 season after testing positive for the banned supplement ephedra.

Parkinson's disease (also known as *Parkinson disease* or *PD*) is a degenerative disorder of the central nervous system that often impairs the sufferer's motor skills and speech.

Parkinson's disease belongs to a group of conditions called movement disorders. It is often characterized by muscle rigidity, tremor, a slowing of physical movement (bradykinesia), and in extreme cases, a loss of physical movement (akinesia). The primary symptoms are the results of excessive muscle contraction, normally caused by the insufficient formation and action of dopamine, which is produced in the dopaminergic neurons of the brain. Secondary symptoms may include high level cognitive dysfunction and subtle language problems. PD is both chronic, meaning it persists over a long period of time, and progressive.

PD is the most common cause of parkinsonism, a group of similar symptoms. PD is also called "primary parkinsonism" or "idiopathic PD" ("idiopathic" meaning of no known cause). While most forms of parkinsonism are idiopathic, there are some cases where the symptoms may result from toxicity, drugs, genetic mutation, head trauma, or other medical disorders.

History

Symptoms of Parkinson's disease have been known and treated since ancient times.[1] However, it was not formally recognised and its symptoms were not documented until 1817 in An Essay on the Shaking Palsy[2] by the British physician James Parkinson. Parkinson's disease was then known as paralysis agitans. The underlying biochemical changes in the brain were identified in the 1950s, due largely to the work of Swedish scientist Arvid Carlsson who later went on to win a Nobel Prize. L-dopa entered clinical practice in 1967[3], and the first study reporting improvements in patients with Parkinson's disease resulting from treatment with L-dopa was published in 1968.[4]

Symptoms

Parkinson disease affects movement (motor symptoms). Typical other symptoms include disorders of mood, behavior, thinking, and sensation (non-motor symptoms). Individual patients' symptoms may be quite dissimilar; progression is also distinctly individual.

Motor symptoms

The cardinal symptoms are:

- tremor: normally 4-7Hz tremor, maximal when the limb is at rest, and decreased with voluntary movement. It is typically unilateral at onset. This is the most apparent and well-known symptom, though an estimated 30% of patients have little perceptible tremor; these are classified as akinetic-rigid.
- rigidity: stiffness; increased muscle tone. In combination with a resting tremor, this produces a ratchety, "cogwheel" rigidity when the limb is passively moved.
- bradykinesia/akinesia: respectively, slowness or absence of movement. Rapid, repetitive movements produce a dysrhythmic and decremental loss of amplitude. Also "dysdiadokinesia", which is the loss of ability to perform rapid alternating movements
- postural instability: failure of postural reflexes, which leads to impaired balance and falls.

Other motor symptoms include:

- Gait and posture disturbances:
    - Shuffling: gait is characterized by short steps, with feet barely leaving the ground, producing an audible shuffling noise. Small obstacles tend to trip the patient
    - Decreased arm swing: a form of bradykinesia
    - Turning "en bloc": rather than the usual twisting of the neck and trunk and pivoting on the toes, PD patients keep their neck and trunk rigid, requiring multiple small steps to accomplish a turn.
    - Stooped, forward-flexed posture. In severe forms, the head and upper shoulders may be bent at a right angle relative to the trunk (camptocormia).

- Festination: a combination of stooped posture, imbalance, and short steps. It leads to a gait that gets progressively faster and faster, often ending in a fall.
- Gait freezing: "freezing" is another word for akinesia, the inability to move. Gait freezing is characterized by inability to move the feet, especially in tight, cluttered spaces or when initiating gait.
- Dystonia (in about 20% of cases): abnormal, sustained, painful twisting muscle contractions, usually affecting the foot and ankle, characterized by toe flexion and foot inversion, interfering with gait. However, dystonia can be quite generalized, involving a majority of skeletal muscles; such episodes are acutely painful and completely disabling.

- Speech and swallowing disturbances
  - Hypophonia: soft speech. Speech quality tends to be soft, hoarse, and monotonous.
  - Festinating speech: excessively rapid, soft, poorly-intelligible speech.
  - Drooling: most likely caused by a weak, infrequent swallow and stooped posture.
  - Non-motor causes of speech/language disturbance in both expressive and receptive language: these include decreased verbal fluency and cognitive disturbance especially related to comprehension of emotional content of speech and of facial expression[5]
  - Dysphagia: impaired ability to swallow. Can lead to aspiration, pneumonia, and ultimately death.
- Other motor symptoms:
  - fatigue (up to 50% of cases);
  - masked facies (a mask-like face also known as hypomimia), with infrequent blinking;[6]
  - difficulty rolling in bed or rising from a seated position;
  - micrographia (small, cramped handwriting);
  - impaired fine motor dexterity and coordination;
  - impaired gross motor coordination;
  - Poverty of movement: overall loss of accessory movements, such as decreased arm swing when walking, as well as spontaneous movement.

Non-motor symptoms

Mood disturbances

- Estimated prevalence rates of depression vary widely according to the population sampled and methodology used. Reviews of depression estimate its occurrence in anywhere from 20-80% of cases.[7] Estimates from community samples tend to find lower rates than from specialist centres. Most studies use self-report questionnaires such as the Beck Depression Inventory which may

overinflate scores due to physical symptoms. Studies using diagnostic interviews by trained psychiatrists also report lower rates of depression.

- More generally, there is an increased risk for any individual with depression to go on to develop Parkinson's disease at a later date.[8]
- Seventy percent of individuals with Parkinson's disease diagnosed with pre-existing depression go on to develop anxiety. Ninety percent of Parkinson's disease patients with pre-existing anxiety subsequently develop depression); apathy or abulia.

Cognitive disturbances

- slowed reaction time; both voluntary and involuntary motor responses are significantly slowed.
- executive dysfunction, characterized by difficulties in: differential allocation of attention, impulse control, set shifting, prioritizing, evaluating the salience of ambient data, interpreting social cues, and subjective time awareness. This complex is present to some degree in most Parkinson's patients; it may progress to:
- dementia: a later development in approximately 20-40% of all patients, typically starting with slowing of thought and progressing to difficulties with abstract thought, memory, and behavioral regulation.
- memory loss; procedural memory is more impaired than declarative memory. Prompting elicits improved recall.
- medication effects: some of the above cognitive disturbances are improved by dopaminergic medications, while others are actually worsened [9]

Sleep disturbances

- Excessive daytime somnolence;
- Initial, intermediate, and terminal insomnia;
- Disturbances in REM sleep: disturbingly vivid dreams, and REM Sleep Disorder, characterized by acting out of dream content;

Sensation disturbances

- impaired visual contrast sensitivity, spatial reasoning, colour discrimination, convergence insufficiency (characterized by double vision) and oculomotor control
dizziness and fainting; usually attributable orthostatic hypotension, a failure of the autonomous nervous system to adjust blood pressure in response to changes in body position

- impaired proprioception (the awareness of bodily position in three-dimensional space)
- reduction or loss of sense of smell (microsmia or anosmia),
- pain: neuropathic, muscle, joints, and tendons, attributable to tension, dystonia, rigidity, joint stiffness, and injuries associated with attempts at accommodation

Autonomic disturbances

- oily skin and seborrheic dermatitis
- urinary incontinence, typically in later disease progression
- constipation and gastric dysmotility that is severe enough to endanger comfort and even health
- altered sexual function: characterized by profound impairment of sexual arousal, behavior, orgasm, and drive is found in mid and late Parkinson disease. Current data addresses male sexual function almost exclusively
- weight loss, which is significant over a period of ten years - 8% of body weight lost compared with 1% in a control group.

Diagnosis

There are currently no blood or laboratory tests that have been proven to help in diagnosing sporadic PD. Therefore the diagnosis is based on medical history and a neurological examination. The disease can be difficult to diagnose accurately. The Unified Parkinson's Disease Rating Scale is the primary clinical tool used to assist in diagnosis and determine severity of PD. Indeed, only 75% of clinical diagnoses of PD are confirmed at autopsy[10]. Early signs and symptoms of PD may sometimes be dismissed as the effects of normal aging. The physician may need to observe the person for some time until it is apparent that the symptoms are consistently present. Usually Doctors look for shuffling of feet and lack of swing in the arms. Doctors may sometimes request brain scans or laboratory tests in order to rule out other diseases. However, CT and MRI brain scans of people with PD usually appear normal.

Descriptive epidemiology

Parkinson's disease is widespread, with a prevalence estimated between 100 and 250 cases per 100,000 in North America; globally prevalence estimates range from a low of 15 per 100,000 in China to a high of 657 per 100,000 in Argentina. Because prevalence rates can be affected by socio-ecomically driven differences in survival as well as biased by survey technique problems [11] , incidence is a more sensitive indicator: rates have ranged from 1.5 per 100,000 in China to a high of 14.8 per 100,000 in Finland.[12] Incidence has been estimated by several groups. A study carried out in northern California[13] observed an age and sex corrected incidence of 13.4 per 100,000/year. The study authors noted a rapid increase in incidence with age, male rates nearly double female rates, and an elevated rate

amongst Hispanics. A study in Spain[14] (of a population of people aged 65 to 85) calculated incidence, adjusted for age and sex, of 186.8/100,000 per year, with men's rates being 2.55 times that of women. For the same age group, the northern California study observed an incidence of roughly 120/100,000/year. A Dutch study[15], published in the same year, noted age-specific incidence rates from 0.3 per 1000 person-years in subjects aged 55 to 65 years, to 4.4 per 1000 person-years for those aged e85 year, and a sex ratio of 1.55 for male incidence.

Cases of PD are reported at all ages, though it is quite rare in people younger than 40 and the average age at which symptoms begin is 58-60; it is principally a disease of the elderly. It occurs in all parts of the world, but appears to be more common in people of European ancestry than in those of African ancestry. Those of East Asian ancestry have an intermediate risk. It is more common in rural than urban areas and men are affected slightly more often than women. It is highly unusual for people under 40 to develop Parkinson's Disease, and twin studies (Tanner)[16]. have shown such disease to be almost entirely genetically caused.

Related diseases

There are other disorders that are called Parkinson-plus diseases. These include:

- Multiple system atrophy (MSA)
  - Shy-Drager syndrome (SDS)
  - Striatonigral degeneration (SND)
  - Olivopontocerebellar atrophy (OPCA)
- Progressive supranuclear palsy (PSP)
- Corticobasal degeneration (CBD)

Some people include dementia with Lewy bodies (DLB) as one of the 'Parkinson-plus' syndromes. Although idiopathic Parkinson's disease patients also have Lewy bodies in their brain tissue, the distribution is denser and more widespread in DLB. Even so, the relationship between Parkinson disease, Parkinson disease with dementia (PDD) and dementia with Lewy bodies (DLB) might be most accurately conceptualized as a spectrum, with a discrete area of overlap between each of the three disorders. The natural history and role of Lewy bodies is very little understood.

Patients often begin with typical Parkinson's disease symptoms which persist for some years; these Parkinson-plus diseases can only be diagnosed when other symptoms become apparent with the passage of time. These Parkinson-plus diseases usually progress more quickly than typical ideopathic Parkinson disease. The usual anti-Parkinson's medications are typically either less effective or not effective at all in controlling symptoms; patients may be exquisitely sensitive to neuroleptic medications like haloperidol. Additionally, the cholinesterase inhibiting medications have shown preliminary efficacy in treating the cognitive, psychiatric, and behavioral aspects of the disease, so correct differential diagnosis is important.

Wilson's disease (hereditary copper accumulation) may present with parkinsonistic features; young patients presenting with parkinsonism may be screened for this rare condition. Essential tremor is often mistaken for Parkinson's disease but usually lacks all features besides tremor.

Pathology

The symptoms of Parkinson's disease result from the loss of pigmented dopamine-secreting (dopaminergic) cells and subsequent loss of melanin, secreted by the same cells, in the pars compacta region of the substantia nigra (literally "black substance"). These neurons project to the striatum and their loss leads to alterations in the activity of the neural circuits within the basal ganglia that regulate movement, in essence an inhibition of the direct pathway and excitation of the indirect pathway.

The direct pathway facilitates movement and the indirect pathway inhibits movement, thus the loss of these cells leads to a hypokinetic movement disorder. The lack of dopamine results in increased inhibition of the ventral lateral nucleus of the thalamus, which sends excitatory projections to the motor cortex, thus leading to hypokinesia.

There are four major dopamine pathways in the brain; the nigrostriatal pathway, referred to above, mediates movement and is the most conspicuously affected in early Parkinson's disease. The other pathways are the mesocortical, the mesolimbic, and the tuberoinfundibular. These pathways are associated with, respectively: volition and emotional responsiveness; desire, initiative, and reward; and sensory processes and maternal behavior. Disruption of dopamine along the non-striatal pathways likely explains much of the neuropsychiatric pathology associated with Parkinson's disease.

The mechanism by which the brain cells in Parkinson's are lost may consist of an abnormal accumulation of the protein alpha-synuclein bound to ubiquitin in the damaged cells. The alpha-synuclein-ubiquitin complex cannot be directed to the proteosome. This protein accumulation forms proteinaceous cytoplasmic inclusions called Lewy bodies. Latest research on pathogenesis of disease has shown that the death of dopaminergic neurons by alpha-synuclein is due to a defect in the machinery that transports proteins between two major cellular organelles — the endoplasmic reticulum (ER) and the Golgi apparatus. Certain proteins like Rab1 may reverse this defect caused by alpha-synuclein in animal models.[17]

Excessive accumulations of iron, which are toxic to nerve cells, are also typically observed in conjunction with the protein inclusions. Iron and other Transition metals such as copper bind to neuromelanin in the affected neurons of the Substantia nigra. So, neuromelanin may be acting as a protective agent. Alternately, neuromelanin (an electronically active semiconductive polymer) may play some other role in neurons.[18] That is, coincidental excessive accumulation of transition metals, etc. on neuromelanin may figure in the differential dropout of pigmented neurons in Parkinsonism. The most likely mechanism is generation of Reactive oxygen species.[19]

Iron induces aggregation of synuclein by oxidative mechanisms.[20] Similarly, dopamine and the byproducts of dopamine production enhance alpha-synuclein aggregation. The precise mechanism whereby such aggregates of alpha-synuclein damage the cells is not known. The aggregates may be merely a normal reaction by the cells as part of their effort to correct a different, as-yet unknown, insult. Based on this mechanistic hypothesis, a transgenic mouse model of Parkinson's has been generated by introduction of human wild-type ±-synuclein into the mouse genome under control of the platelet-derived-growth factor-^{2} promoter. [21]

Causes of Parkinson's disease

Most people with Parkinson's disease are described as having idiopathic Parkinson's disease (having no specific cause). There are far less common causes of Parkinson's disease including genetic, toxins, head trauma, and drug-induced Parkinson's disease.

Genetic

In recent years, a number of specific genetic mutations causing Parkinson's disease have been discovered, including in certain populations (Contursi, Italy). These account for a small minority of cases of Parkinson's disease. Somebody who has Parkinson's disease is more likely to have relatives that also have Parkinson's disease. However, this does not mean that the disorder has been passed on genetically.

Genetic forms that have been identified include:

external links in this section are to OMIM

- PARK1 (OMIM #168601), caused by mutations in the SNCA gene, which codes for the protein alpha-synuclein. PARK1 causes autosomal dominant Parkinson disease. So-called PARK4 is probably caused by triplication of SNCA.[22]
- PARK2 (OMIM *602544), caused by mutations in protein parkin. Parkin mutations may be one of the most common known genetic causes of early-onset Parkinson disease. In one study, of patients with onset of Parkinson disease prior to age 40 (10% of all PD patients), 18% had parkin mutations, with 5% homozygous mutations.[23] Patients with an autosomal recessive family history of parkinsonism are much more likely to carry parkin mutations if age at onset is less than 20 (80% vs. 28% with onset over age 40).[24]Patients with parkin mutations (PARK2) do not have Lewy bodies. Such patients develop a syndrome that closely resembles the sporadic form of PD; however, they tend to develop symptoms at a much younger age.
- PARK3 (OMIM %602404), mapped to 2p, autosomal dominant, only described in a few kindreds.
- PARK5, caused by mutations in the UCHL1 gene (OMIM +191342) which codes for the protein ubiquitin carboxy-terminal hydrolase L1
- PARK6 (OMIM #605909), caused by mutations in PINK1 (OMIM *608309) which codes for the protein PTEN-induced putative kinase 1.
- PARK7 (OMIM #606324), caused by mutations in DJ-1 (OMIM 602533)
- PARK8 (OMIM #607060), caused by mutations in LRRK2 which codes for the protein dardarin. In vitro, mutant LRRK2 causes protein aggregation and cell death, possibly through an interaction with parkin.[25] LRRK2 mutations, of which the most common is G2019S, cause autosomal dominant Parkinson disease, with a penetrance of nearly 100% by age 80.[26] G2019S is the most common known genetic cause of Parkinson disease, found in 1-6% of U.S. and

European PD patients.[27] It is especially common in Ashkenazi Jewish patients, with a prevalence of 29.7% in familial cases and 13.3% in sporadic.[28]

- PARK12 (OMIM %300557), maps to the X chromosome

Toxins

One theory holds that the disease may result in many or even most cases from the combination of a genetically determined vulnerability to environmental toxins along with exposure to those toxins.[29] This hypothesis is consistent with the fact that Parkinson's disease is not distributed homogenously throughout the population: rather, its incidence varies geographically. It would appear that incidence varies by time as well, for although the later stages of untreated PD are distinct and readily recognizable, the disease was not remarked upon until the beginnings of the Industrial Revolution, and not long thereafter become a common observation in clinical practice. The toxins most strongly suspected at present are certain pesticides and transition-series metals such as manganese or iron, especially those that generate reactive oxygen species,[19] [30] and or bind to neuromelanin, as originally suggested by G.C. Cotzias. [31] [32] MPTP is used as a model for Parkinson's as it can rapidly induce parkinsonian symptoms in human beings and other animals, of any age. MPTP was notorious for a string of Parkinson's disease cases in California in 1982 when it contaminated the illicit production of the synthetic opiate MPPP. Its toxicity likely comes from generation of reactive oxygen species. [33]

Other toxin-based models employ PCBs,[34] paraquat[35] (a herbicide) in combination with maneb (a fungicide) [36] rotenone[37] (an insecticide), and specific organochlorine pesticides including dieldrin[38] and lindane.[39] Numerous studies have found an increase in Parkinson disease in persons who consume rural well water; researchers theorize that water consumption is a proxy measure of pesticide exposure. In agreement with this hypothesis are studies which have found a dose-dependent an increase in PD in persons exposed to agricultural chemicals.

Almost all of the PD-causing toxins act on the mitochondrial complex I of the electron transfer chain, and sporadic PD cases have been found to have a partial loss of activity of this enzyme complex. Studies in cybrids have found that mitochondrial DNA, rather than nuclear DNA, is responsible for the dysfunction. Most recently, microheteroplasmic mutations in one of the mitochondrial complex I genes, ND5, were found to be sufficient to diagnose sporadic PD correctly in 27 out of 28 cases. While additional studies are needed, mitochondrial microheteroplasmic mutations may be the cause of the majority of PD cases.

However, the ubiquity of agricultural chemical exposures makes it difficult to gauge the true extent of the problem. In the current state of knowledge about the origins of the disease, it appears that family history of the disease and (especially) multiple episodes of head-trauma-induced unconsciousness increase individual risk more than does pesticide exposure, but research is continuing.

Head trauma

Past episodes of head trauma are reported more frequently by sufferers than by others in the population.[40][41][42] A methodologically strong recent study[40] found that those who have experienced a head injury are four times more likely to develop Parkinson’s disease than those who have never suffered a head injury. The risk of developing Parkinson’s increases eightfold for patients who have had head trauma requiring hospitalization, and it

increases 11-fold for patients who have experienced severe head injury. The authors comment that since head trauma is a rare event, the contribution to PD incidence is slight. They express further concern that their results may be biased by recall, i.e., the PD patients because they reflect upon the causes of their illness, may remember head trauma better than the non-ill control subjects.

These limitations were overcome recently by Tanner and colleagues [43], who found a similar risk of 3.8, with increasing risk associated with more severe injury and hospitalization.

Drug-induced

Antipsychotics, which are used to treat schizophrenia and psychosis, can induce the symptoms of Parkinson's disease (or parkinsonism) by lowering dopaminergic activity. Due to feedback inhibition, L-dopa can also eventually cause the symptoms of Parkinson's disease that it initially relieves. Dopamine agonists can also eventually contribute to Parkinson's disease symptoms by increasing the sensitivity of dopamine receptors.

Treatment

Parkinson's disease is a chronic disorder that requires broad-based management including patient and family education, support group services, general wellness maintenance, exercise, and nutrition. At present, there is no cure for PD, but medications or surgery can provide relief from the symptoms.

Levodopa

The most widely used form of treatment is L-dopa in various forms. L-dopa is transfomed into dopamine in the dopaminergic neurons by L-aromatic amino acid decarboxylase (often known by its former name dopa-decarboxylase). However, only 1-5% of L-DOPA enters the dopaminergic neurons. The remaining L-DOPA is often metabolised to dopamine elsewhere, causing a wide variety of side effects. Due to feedback inhibition, L-dopa results in a reduction in the endogenous formation of L-dopa, and so eventually becomes counterproductive.

Carbidopa and benserazide are dopa decarboxylase inhibitors. They help to prevent the metabolism of L-dopa before it reaches the dopaminergic neurons and are generally given as combination preparations of carbidopa/levodopa (co-careldopa) (e.g. Sinemet, Parcopa) and benserazide/levodopa (co-beneldopa) (e.g. Madopar). There are also controlled release versions of Sinemet and Madopar that spread out the effect of the L-dopa. Duodopa is a combination of levodopa and carbidopa, dispersed as a viscous gel. Using a patient-operated portable pump, the drug is continuously delivered via a tube directly into the upper small intestine, where it is rapidly absorbed.

Talcopone inhibits the COMT enzyme, thereby prolonging the effects of L-dopa, and so has been used to complement L-dopa. However, due to its possible side effects such as liver failure, it's limited in its availability.

A similar drug, entacapone, has similar efficacy and has not been shown to cause significant alterations of liver function. A recent follow-up study by Cilia and colleagues looked at the clinical effects of long-term administration of entacapone on motor performance and pharmacological compensation is advanced PD patients with motor fluctuations. 47 patients with advanced PD and motor fluctuations were followed for six years from the first prescription of entacapone and showed a stabilization of motor conditions, reflecting entacapone can maintain adequate inhibition of COMT over time [44].

Mucuna pruriens, is a natural source of therapeutic quantities of L-dopa.

Dopamine agonists

The dopamine-agonists bromocriptine (Parlodel), pergolide (Permax), pramipexole (Mirapex), ropinirole (Requip), cabergoline (Cabaser), apomorphine (Apokyn), and lisuride (Revanil), are moderately effective. These have their own side effects including those listed above in addition to somnolence, hallucinations and /or insomnia. Dopamine agonists initially act by stimulating some of the dopamine receptors. However, they cause the dopamine receptors to become progressively less sensitive, thereby eventually increasing the symptoms.

Dopamine agonists can be useful for patients experiencing on-off fluctuations and dyskinesias as a result of high doses of L-dopa. Apomorphine can be administered via subcutaneous injection using a small pump which is carried by the patient. A low dose is automatically administered throughout the day, reducing the fluctuations of motor symptoms by providing a steady dose of dopaminergic stimulation. After an initial "apomorphine challenge" in hospital to test its effectiveness and brief patient and caregiver, the primary caregiver (often a spouse or partner) takes over maintenance of the pump. The injection site must be changed daily and rotated around the body to avoid the formation of nodules. Apomorphine is also available in a more acute dose as an autoinjector pen for emergency doses such as after a fall or first thing in the morning.

MAO-B inhibitors

Selegiline (Eldepryl) and rasagiline (Azilect) reduce the symptoms by inhibiting monoamine oxidase-B (MAO-B), which inhibits the breakdown of dopamine secreted by the dopaminergic neurons. By-products of selegiline include amphetamine and methamphetamine, which can cause side effects such as insomnia. Use of L-dopa in conjunction with selegiline has increased mortality rates that have not been effectively explained. Another side effect of the combination can be stomatitis. One report raised concern about increased mortality when MAO-B inhibitors were combined with L-dopa [45]; however subsequent studies have not confirmed this finding[46]. Unlike other non selective monoamine oxidase inhibitors, tyramine-containing foods do not cause a hypertensive crisis.

Surgical interventions

Treating PD with surgery was once a common practice. But after the discovery of levodopa, surgery was restricted to only a few cases. Studies in the past few decades have led to great improvements in surgical techniques, and surgery is again being used in people with advanced PD for whom drug therapy is no longer sufficient. Deep brain stimulation is presently the most used surgical means of treatment, but other surgical therapies that have shown promise include surgical lesion of the subthalamic nucleus[47] and of the internal segment of the globus pallidus, a procedure known as pallidotomy.[48].

Speech therapies

The most widely practiced treatment for the speech disorders associated with Parkinson's disease is Lee Silverman Voice Treatment (LSVT). LSVT focuses on increasing vocal loudness.[49]

A study found that an electronic device providing frequency-shifted auditory feedback (FAF) improved the clarity of Parkinson's patients' speech.[50]

Physical exercise

Regular physical exercise and/or therapy, including in forms such as yoga, tai chi, and dance can be beneficial to the patient for maintaining and improving mobility, flexibility, balance and a range of motion.

Methods undergoing evaluation

Gene therapy

Currently under investigation is gene therapy. This involves using a harmless virus to shuttle a gene into a part of the brain called the subthalamic nucleus (STN). The gene used leads to the production of an enzyme called glutamic acid decarboxylase (GAD), which catalyses the production of a neurotransmitter called GABA. GABA acts as a direct inhibitor on the overactive cells in the STN.

GDNF infusion involves the infusion of GDNF (glial-derived neurotrophic factor) into the basal ganglia using surgically implanted catheters. Via a series of biochemical reactions, GDNF stimulates the formation of L-dopa. GDNF therapy is still in development.

In the future, implantation of cells genetically engineered to produce dopamine or stem cells that transform into dopamine-producing cells may become available. Even these, however, will not constitute cures because they do not address the considerable loss of activity of the dopaminergic neurons.

Neuroprotective treatments

Neuroprotective treatments are at the forefront of PD research - presenting many new challenges. These agents protect neurons from cell death induced by disease presence resulting in a slower pregression of disease. Agents currently under investigation as neuroprotective agents include apoptotic drugs (CEP 1347 and CTCT346), lazaroids, bioenergetics, antiglutamatergic agents and dopamine receptors [51]

Neural transplantation

The first prospective randomised double-blind sham-placebo controlled trial of dopaminergic transplants failed to show an improvement in quality of life although some significant clinical improvements were seen in patients below the age of 60 [52]

Nutrients

Nutrients have been used in clinical studies and are widely used by people with Parkinson's disease in order to partially treat Parkinson's disease or slow down its deterioration. The L-dopa precursor L-tyrosine was shown to relieve an average of 70% of symptoms.[53] Ferrous iron, the essential cofactor for L-dopa biosynthesis was shown to relieve between 10% and 60% of symptoms in 110 out of 110 patients.[54][55]

More limited efficacy has been obtained with the use of THFA, NADH, and pyridoxine—coenzymes and coenzyme precursors involved in dopamine biosynthesis[56]. Vitamin C and vitamin E in large doses are commonly used by patients in order to theoretically lessen the cell damage that occurs in Parkinson's disease. This is because the enzymes superoxide dismutase and catalase require these vitamins in order to nullify the superoxide anion, a toxin commonly produced in damaged cells. However, in the randomized controlled trial, DATATOP of patients with early PD, no beneficial effect for vitamin E compared to placebo was seen[57]

Coenzyme Q10 has more recently been used for similar reasons. MitoQ is a newly developed synthetic substance that is similar in structure and function to coenzyme Q10. However, proof of benefit has not been demonstrated yet.

Qigong

There have been two methodologically acceptable studies looking at qigong in Parkinson's disease. In a trial in Bonn, a open-label randomised pilot study in 56 patients found an improvement in motor and non-motor symptoms amongst patients who had undergone one hour of structured Qigong exercise per week in two 8-week blocks. The authors speculate that visualizing the flow of "energy" might act as an internal cue and so help improve movement. [58]

The second study, however, found Qigong to be ineffective in treating Parkinson's disease. In that study, researchers used a randomized cross-over trial to compare aerobic training with Qigong in advanced Parkinson's disease. Two groups of PD patients were assessed, had 20 sessions of either aerobic exercise or qigong, were assessed again, then after a 2 month gap were switched over for another 20 sessions, and finally assessed again. The authors found an improvement in motor ability and cardiorespiratory function following aerobic exercise, but found no benefit following Qigong. The authors also point out that aerobic exercise had no benefit for patients' quality of life. [59]

Prognosis

PD is not by itself a fatal disease, but it does get worse with time. The average life expectancy of a PD patient is generally lower than for people who do not have the disease[60]. In the late stages of the disease, PD may cause complications such as choking, pneumonia, and falls that can lead to death.

The progression of symptoms in PD may take 20 years or more. In some people, however, the disease progresses more quickly. There is no way to predict what course the disease will take for an individual person. One commonly used system for describing how the symptoms of PD progress is called the Hoehn and Yahr scale.

Another commonly used scale is the Unified Parkinson's Disease Rating Scale (UPDRS). This much more complicated scale has multiple ratings that measure mental functioning, behavior, and mood; activities of daily living; and motor function. Both the Hoehn and Yahr scale and the UPDRS are used to measure how individuals are faring and how much treatments are helping them. It should be noted that neither scale is specific to Parkinson's Disease; that patients with other illnesses can score in the Parkinson's range.

With appropriate treatment, most people with PD can live productive lives for many years after diagnosis.

Notable Parkinson's sufferers

One famous sufferer of young-onset Parkinson's is Michael J. Fox, who has written a book about his experience of the disease and established The Michael J. Fox Foundation for Parkinson's Research to develop a cure for Parkinson's disease within this decade.

Other famous sufferers include Pope John Paul II, playwright Eugene O'Neill, artist Salvador Dalí, evangelist Billy Graham, former US Attorney General Janet Reno, boxer Muhammad Ali, dictators Adolf Hitler, Franco and Mao Zedong, and numerous actors such as Terry-Thomas, Deborah Kerr, Kenneth More, Vincent Price and Michael Redgrave.

The film Awakenings (starring Robin Williams and Robert De Niro and based on genuine cases reported by Oliver Sacks) deals sensitively and largely accurately with a similar disease, postencephalitic parkinsonism.

Dopamine agonists

A *dopamine agonist* is a compound that activates dopamine receptors, mimicking the effect of the neurotransmitter dopamine. Some medical drugs act as dopamine agonists; they are typically used for treating Parkinson's disease, and may be useful for restless legs syndrome (RLS).

- Agonist

Antiplatelet drugs

An *antiplatelet drug* is a member of a class of pharmaceuticals that decreases platelet aggregation and inhibits thrombus formation. They are effective in the arterial circulation, where anticoagulants have little effect.

They are widely used in primary and secondary prevention of thrombotic cerebrovascular or cardiovascular disease.

Choice of antiplatelet drug

A recent review [1] states: "....low-dose aspirin increases the risk of major bleeding 2-fold compared with placebo. However, the annual incidence of major bleeding due to low-dose aspirin is modest—only 1.3 patients per thousand higher than what is observed with placebo treatment. Treatment of approximately 800 patients with low-dose aspirin annually for cardiovascular prophylaxis will result in only 1 additional major bleeding episode." Further, "...the cost to prevent one major GI bleeding episode from aspirin in 1 year by substituting clopidogrel therapy would be $1,216,180..."

Antiplatelet drugs

The most important antiplatelet drugs are:

- Cyclooxygenase inhibitors
  - Aspirin
- Adenosine diphosphate receptor inhibitors
  - Clopidogrel **(Plavix)**
  - Ticlopidine (Ticlid)
- Phosphodiesterase inhibitors
  - Cilostazol (Pletal)
- Glycoprotein IIB/IIIA inhibitors **(intravenous use only)**
  - Abciximab (ReoPro)
  - Eptifibatide (Integrilin)
  - Tirofiban (Aggrastat)
- Adenosine reuptake inhibitors
  - Dipyridamole (Persantine)

Systematic (IUPAC) name

(+)-(S)-methyl 2-(2-chlorophenyl)-2-(6,7-dihydrothieno[3,2-c]pyridin-5(4H)-yl)acetate

Identifiers

CAS number 113665-84-2

ATC code **B01**AC04

PubChem 60606

DrugBank APRD00444

Chemical data

Formula C***16***H***16***ClNO***2***S

Mol. weight 321.82

Pharmacokinetic data

Bioavailability >50%

Metabolism hepatic

Half life 7–8 hours (inactive metabolite)

Excretion 50% renal, 46% biliary

Therapeutic considerations

Pregnancy cat. $B1_{(AU)}$ $B_{(US)}$

Legal status $S4_{(AU)}$ $POM_{(UK)}$ $_{\text{-only(US)}}$

Routes oral

Clopidogrel is a potent oral antiplatelet agent often used in the treatment of coronary artery disease, peripheral vascular disease, and cerebrovascular disease. It is marketed by Bristol-Myers Squibb and Sanofi-Aventis under the trade name *Plavix*. It is also marketed in the generic form by Apotex, a Canadian generic pharmaceutical company, though an injunction to withhold further shipments of their form is in effect while patent issues are

dealt with. In 2005 it was the world's second highest selling pharmaceutical with sales of US$5.9 billion.

Pharmacology

The mechanism of action of clopidogrel is irreversible blockade of the adenosine diphosphate (ADP) receptor on platelet cell membranes. This receptor is named P2Y12 and is important in platelet aggregation, the cross-linking of platelets by fibrin. The blockade of this receptor inhibits platelet aggregation by blocking activation of the glycoprotein IIb/IIIa pathway.

Platelet inhibition can be demonstrated two hours after a single dose of oral clopidogrel.

Clinical use

Indications

Clopidogrel is indicated for (Rossi, 2006):

- Prevention of vascular ischaemic events in patients with symptomatic atherosclerosis
- Acute coronary syndrome without ST-segment elevation (NSTEMI), along with aspirin

It is also used, along with aspirin, for the prevention of thromboembolism after placement of intracoronary stent. (Rossi, 2006)

Most consensus-based therapeutic guidelines recommend the use of clopidogrel, over aspirin, in patients requiring antiplatelet therapy but with a history of gastric ulceration, due to the lower incidence of gastric ulceration associated with the use of clopidogrel vs aspirin. A recent study has shown that in patients with healed aspirin-induced ulcers, however, patients receiving aspirin plus the proton pump inhibitor esomeprazole had a lower incidence of recurrent ulcer bleeding than patients receiving clopidogrel. (Chan et al., 2005)

Dosage forms

Clopidogrel is marketed as *clopidogrel bisulfate* (*clopidogrel hydrogen sulfate*), most commonly under the trade name *Plavix*, as 75 mg tablets.

Adverse effects

Serious adverse drug reactions associated with clopidogrel therapy include:

- Severe neutropenia (Incidence: 5/10,000)
- Thrombotic thrombocytopenic purpura (TTP) (Incidence: 4/1,000,000 patients treated)
- Hemorrhage - The incidence of hemorrhage may be increased by the co-administration of aspirin.
    - Gastrointestinal Hemorrhage (Incidence: 2.0%)

  - Cerebral Hemorrhage (Incidence: 0.1 to 0.4%)

Antipsychotics

The term *antipsychotic* is applied to a group of drugs used to treat psychosis. Common conditions with which antipsychotics might be used include schizophrenia, mania and delusional disorder, although antipsychotics might be used to counter psychosis associated with a wide range of other diagnoses. Antipsychotics also have some effects as mood stabilizers, leading to their frequent use in treating mood disorder (particularly bipolar disorder) even when no signs of psychosis are present. Some antipsychotics (haloperidol, pimozide) are used off-label to treat Tourette syndrome.

Antipsychotics are also referred to as *neuroleptic drugs*, or simply *neuroleptics*. The word neuroleptic is derieved from Greek. 'Neuro' refers to the nerves and 'lept' means 'to take hold of'. Thus the word means 'taking hold of one's nerves' which implies their role in mood stabilization.

There are currently two main types of antipsychotics in use, the typical antipsychotics and atypical antipsychotics. A new class of antipsychotic drugs has recently been discovered, known as dopamine partial agonists. Clinical development has progressed rapidly on partial dopamine agonists, and one drug in this class (aripiprazole) has already been approved by the Food and Drug Administration. Although the underlying mechanism of this new class is different from all previous typical and atypical antipsychotics, dopamine partial agonists are often categorized as atypicals.

Typical antipsychotics are sometimes referred to as *major tranquilizers*, due to the fact that some of them can tranquilize and sedate. This term is increasingly disused because many newer antipsychotics do not have strong sedating properties and the terminology implies a connection with benzodiazepines, whereas none exists.

Common antipsychotic drugs

Commonly used antipsychotic medications are listed below by drug group. Trade names appear in brackets.

- Typical antipsychotics:
    - Phenothiazines:
        - Chlorpromazine (Thorazine®)

        Fluphenazine (Prolixin®) - Available in decanoate (long acting) form
        Perphenazine (Trilafon®)
        Prochlorperazine (Compazine®)
        Thioridazine (Mellaril®)
        Trifluoperazine (Stelazine®)
- Butyrophenones
    - Haloperidol (Haldol®) - Available in decanoate (long acting) form
    - Droperidol

Pimozide (Orap®) - Used to treat Tourette syndrome

- Atypical antipsychotics:
  - Clozapine (Clozaril®) - Requires weekly to biweekly CBC (FBC) due to risk of agranulocytosis (a severe decrease of white blood cells).
  - Olanzapine (Zyprexa®) - Used to treat psychotic disorders including acute manic episodes and maintenance of bipolar disorder. Dosing 2.5 mg to 20 mg per day. Comes in a form that quickly dissolves in the mouth (Zyprexa Zydis). May cause appetite increase, weight gain and altered glucose metabolism leading to an increased risk of diabetes mellitus.
  - Risperidone (Risperdal®) - Dosing 0.25 to 6 mg per day and is titrated upward; divided dosing is recommended until initial titration is completed at which time the drug can be administered once daily. Available in long-acting form (Risperdal Consta that is administered every 2 weeks; usual dose is 25 mg). Comes in a form that quickly dissovles in the mouth (Risperdal M-Tab)
  - Quetiapine (Seroquel®) - Used primarily to treat bipolar disorder and schizophrenia, and "off label" to treat chronic insomnia and restless legs syndrome; it is a powerful sedative (if it's used to treat sleep disorders and is not effective at 200 mg, it is not going to be effective in this regard). Dosing starts at 25 mg and continues up to 800 mg maximum per day, depending on the severity of the symptom(s) being treated. Users typically take smaller doses during the day for the neuroleptic properties and larger dose at bedtime for the sedative effects, or divided in two equally high doses every 12 hours (75-400mg bid).
  - Ziprasidone (Geodon®) - Now (2006) approved to treat bipolar disorder. Dosing 20 mg twice daily initially up to 80 mg twice daily. Prolonged QT interval a concern; watch closely with patients who have heart disease; when used with other drugs that prolong QT interval potentially life-threatening.
- Dopamine partial agonists:
  - Aripiprazole (Abilify®) - Among the newest (2006) atypical antipsychotics; dosing 5 mg up to maximum of 30 mg has been used. Mechanism of action is thought to reduce susceptibility to metabolic symptoms seen in some other atypical antipsychotics.
  - Under clinical development - Bifeprunox; norclozapine (ACP-104).
- Other options
  - Symbyax - A combination of olanzapine and fluoxetine used in the treatment of bipolar depression.
  - Tetrabenazine (Nitoman® in Canada and Xenazine® in New Zealand and some parts of Europe) is similar in function to antipsychotic drugs, though isn't generally considered an antipsychotic itself. This is likely due to its main usefulness being the treatment of hyperkinetic movement disorders such as Huntington's Disease and Tourette syndrome, rather than for conditions such as schizophrenia. Also, rather than having the potential to cause tardive dyskinesia that most antipsychotics have, tetrabenazine can actually be an effective treatment for the condition.

The most common antipsychotic drugs are now off-patent, meaning any pharmaceutical company is legally allowed to produce cheap generic versions of these medications. Whilst this makes them a great deal cheaper than the atypical drugs which are still being manufactured under patent constraints, atypical drugs are preferred as a first line treatment due to the fact that they are believed to have fewer side effects and seem to have additional benefits for the 'negative symptoms' of schizophrenia, a typical condition for which they might be prescribed.

Drug action and effectiveness

All antipsychotic drugs tend to block the D_2 receptors in the dopamine pathways in the brain, so the normal effect of dopamine release in the relevant synapses is reduced.

It is the blockade of D_2 receptors in the mesolimbic pathway of the brain which is thought to produce the intended antipsychotic effect.

Typical antipsychotics are not particularly selective and also block the same receptors in the mesocortical pathway, tuberoinfundibular pathway and the nigrostriatal pathway. Blocking D_2 receptors in these other pathways is thought to produce some of the unwanted side effects that the typical antipsychotics can produce (see below).

Atypical antipsychotic drugs have a similar blocking effect on D_2 receptors but seem to be a little more selective, targeting the intended pathway to a larger degree than the others. They also block or partially block serotonin receptors (particularly $5HT_{2A,C}$ and $5HT_{1A}$ receptors).

This combination of effects on both dopamine and serotonin receptors might be why atypical antipsychotic drugs tend to have fewer side effects than typicals and have a seemingly additional effect on the 'negative symptoms' of schizophrenia.

Anti-psychotics can be classified on a spectrum of low potency to high potency, where potency refers to the ability of the drug to bind to dopamine receptors, and not to the effectiveness of the drug. High potency antipsychotics such as haloperidol typically have doses of a few milligrams and cause less sleepiness and calming effects than low potency antipsychotics such as chlorpromazine, which have dosages of several hundred milligrams.

Some people who become psychotic do not seem to respond to antipsychotic medication, despite studies showing that the drug is blocking the same number of receptors as in other people who do respond to the treatment.

Side effects

The range of interactions can produce different adverse effects including extrapyramidal reactions, including acute dystonias, akathisia, parkinsonism (rigidity and tremor), tardive dyskinesia, tachycardia, hypotension, impotence, lethargy, seizures, and hyperprolactinaemia.

The atypical antipsychotics (especially olanzapine) seem to cause weight gain more commonly than the typical antipsychotics. The well documented metabolic side effects associated with weight gain include diabetes that, not infrequently, can be life threatening.

Clozapine also has a risk of inducing agranulocytosis, a potentially dangerous reduction in the number of white blood cells in the body. Because of this risk, patients prescribed

clozapine may need to have regular blood checks to catch the condition early if it does occur, so the patient is in no danger.

One of the more serious of these side effects is tardive dyskinesia, in which the sufferer may show repetitive, involuntary, purposeless movements often of the lips, face, legs or torso. (Photos and video can be seen here). It is believed that there is a greater risk of developing tardive dyskinesia with the older, typical antipsychotic drugs, although the newer antipsychotics are now also known to cause this disorder. It is believed by some that the risk of tardive dyskinesia can be reduced by combining the anti-psychotics with diphenhydramine or benztropine, though this has not been established. Central nervous system damage is also associated with irreversible tardive akathisia and/or tardive dysphrenia.

A potentially serious side effect of many antipsychotics is that they tend to lower an individuals seizure threshold. Chlorpromazine and clozapine particularly, have a relatively high seizurogenic potential. Fluphenazine, haloperidol, pimozide and risperidone exhibit a relatively low risk. Caution should be exercised in individuals that have a history of seizurogenic conditions (such as epilepsy, or brain damage).

Another serious side effect is neuroleptic malignant syndrome, in which the drugs appear to cause the temperature regulation centers to fail, resulting in a medical emergency as the patient's temperature suddenly increases to dangerous levels.

Another problematic side effect of antipsychotics is dysphoria, meaning that it just makes the patient feel bad. This side-effect is a major problem for patients with schizophrenia in that it causes them to discontinue medication, and this produces a relapse of psychotic symptoms.

Whilst this may seem a daunting list, it must be noted that many people suffer few of the obvious side effects from taking antipsychotic medication. Some side effects, such as subtle cognitive problems, foot rocking, or drooling, in the case of akinesia go unnoticed.

Other symptoms of akinesia of antipsychotics include deterioration of teeth due to a lack of saliva. These symptoms are hard to spot and are often dismissed.

Typical vs Atypical comparison

While the atypical, second-generation medications were marketed as offering greater efficacity in reducing psychotic symptoms while reducting side effects (and extra-pyramidal symptoms in particular) than typical medications, these results showing these effects often lack robustness. To remediate this problem, the NIMH conducted a recent multi-site, double-blind, study (the CATIE project), which was published in 2005. This study compared several atypical antipsychotics to an older typical antipsychotic, perphenazine, among 1493 persons with schizophrenia. Perphenazine was chosen because of its lower potency and moderate side-effect profile. The study found that only olanzapine outperformed perphenazine in the researchers' principal outcome, the discontinuation rate. The authors also noted the apparent superior efficacy of olanzapine to the other drugs for greater reduction in psychopathology, longer duration of successful treatment, and lower rate of hospitalizations for an exacerbation of schizophrenia. In contrast, no other atypical studied (risperidone, quetiapine, and ziprasidone) did better than the typical perphenazine on those measures. Olanzapine, however, was associated with relatively severe metabolic effects: subjects with

olanzapine showed a major weight gain problem and increases in glycose, cholesterol, and triglycerides. The average weight gain (1.1 kg/month, or 44 pounds for the 18 months that lasted the study) casts serious doubt on the potentiality of long-term use of this drug. Perphenazine did not create more extrapyramidal side-effect as measured by rating scales (a result supported by a meta-analysis by Dr. Leucht published in Lancet), although it should be noted that more patients discontinued perphenazine owing to extrapyramidal effects compared to the atypical agents (8 percent vs. 2 percent to 4 percent, P=0.002).

A phase 2 part of this study roughly replicated these findings. This phase consisted on a second randomization of the patients who discontinuated the taking of medication in the first phase. Olanzapine was again the only medication to stand out in the outcome measures, although the results did not always reach statistical significance, in part to the decrease of power. Perphenazine again did not create more extrapyramidal effects.

A subsequent phase was conducted. This phase innovated in allowing clinicians to offer clozapine. Clozapine indeed proved to be more effective at reducing medication drop-outs than other neuroleptic agents. Researchers also observed a trend showing clozapine with a greater reduction of symptoms. However, the potential of clozapine to cause toxic side effects, including agranulocytosis, limits the prescription to persons with schizophrenia.

History and design

The original antipsychotic drugs were happened upon largely by chance and were tested empirically for their effectiveness.

The first antipsychotic was chlorpromazine, which was developed as a surgical anesthetic. It was first used on psychiatric patients in the belief that it would have a calming effect. However, the drug soon appeared to reduce psychosis beyond this calming effect, and now some believe that it causes a reduction of psychosis unrelated to the sedating effect of the medication. It was introduced for the treatment of psychosis during the period when lobotomy was a common treatment and was hailed as a "cure" for schizophrenia. It was then touted to provide a "chemical lobotomy," causing similar neurological effects without requiring surgery.

The newer atypical antipsychotics are supposedly rationally designed drugs in which a theoretical understanding of both the condition to be treated and the effect of certain molecules on the body is used to develop potential new drug candidates.

Atypical antipsychotics

The *atypical antipsychotics* (also known as second generation antipsychotics) are a class of prescription medications used to treat psychiatric conditions. All atypical antipsychotics are FDA approved for use in the treatment of schizophrenia. Some carry FDA approved

indications for acute mania, bipolar mania, psychotic agitation, bipolar maintenance, and other indications.

History

The first atypical antipsychotic medication, clozapine, was discovered in the 1950s, and introduced in clinical practice in the 1970s. Clozapine fell out of popularity due to concerns over drug-induced agranulocytosis. With research indicating its effectiveness in treatment-resistant schizophrenia and the development of an adverse event monitoring system, clozapine reemerged as a viable antipsychotic. Despite the effectiveness of clozapine for treatment-resistant schizophrenia, agents with a more favorable side effect profile were sought after for widespread use. During the 1990s, olanzapine, risperidone, and quetiapine were introduced, with ziprasidone and aripiprazole following in the early 2000s.

The atypical antipsychotics have found favor among clinicians and are now considered to be first line treatments for schizophrenia and are gradually replacing the typical antipsychotics. Most researchers agree that the defining characteristic of an atypical antipsychotic is the decreased propensity of these agents to cause extrapyramidal side effects and an absence of sustained prolactin elevation.

Pharmacology of the atypicals

The mechanism of action of these agents is unknown, and likely differs to some extent among the various drugs within the class. Indeed, the receptor binding profile of the atypical antipsychotics varies quite substantiably, and this variability may be responsible for clinical differences, such as patient response and side effect profile. While modulation of the dopamine neurotransmitter system is necessary for antipsychotic activity, the role of the serotonergic activity of the atypicals is debated. Some researchers believe that D2 receptor antagonism, coupled with 5-HT2A receptor antagonism, is responsible for the "atypicality" of atypical antipsychotics. Others believe that fast dissociation (a fast Koff) from the D2 receptor, allowing for better transmission of normal physiological dopamine surges, better explains the pharmacological evidence.

There is extensive evidence that atypical antipsychotics have less of an affinity for D2 receptors and more of an affinity for the D4 receptors. This is primarily because atypical antipsychotics are somewhat less likely to cause tardive dyskinesia. The idea is that D2 receptors are dopaminergically ubiquitous and affect the motor system as much as the motivational aspect of the dopamine system. On the other hand, D4 is a more accurate dopamine receptor subtype. Atypical antipsychotics also affect the norepinephrine, acetylcholine, and histamine receptors of various subtypes.

Side effects

The side effects reportedly associated with the various atypical antipsychotics vary and are medication-specific. Generally speaking, atypical antipsychotics are associated with fewer extrapyramidal side effects and less propensity for the development of tardive dyskinesia than the typical antipsychotics. In 2004, the Committee for the Safety of Medicines (CSM) in the UK issued a warning that olanzapine and risperidone should not be given to elderly patients with dementia, because of an increased risk of stroke. Sometimes

atypical antipsychotics can cause abnormal shifts in sleep patterns, and extreme tiredness and weakness.

Tardive Dyskinesia

The main advantage to taking atypical antipsychotics over older anti-psychotics (such as Haldol) is the decreased risk of developing tardive dyskinesia. However, all of the atypical antipsychotics warn about the possiblity of tardive dyskinesia in their package inserts and in the PDR. It is not possible to truly know the risks of tardive dyskinesia when taking atypicals, because tardive dyskinesia can take many decades to develop and the atypical antipsychotics are not old enough to have been tested over a long enough period of time to determine all of the long-term risks.

Still, it is safe to say that the atypicals will probably not cause tardive dyskinesia as often as older anti-psychotics do. However, the atypicals may cause serious metabolic disorders to make them equally dangerous as the older anti-psychotic drugs.

Metabolic side effects with atypical antipsychotics

Recently, metabolic concerns have been of grave concern to clinicians, patients and the FDA. In 2003, the Food and Drug Administration (FDA) required all manufacturers of atypical antipsychotics to change their labeling to include a warning about the risks of hyperglycemia and diabetes with atypical antipsychotics. It must also be pointed out that although all atypicals must carry the warning on their labeling, some evidence shows that all atypicals are not equal in their effects of weight and insulin sensitivity. The general consensus is that clozapine and olanzapine are associated with the greatest effects on weight gain and decreased insulin sensitivity, followed by risperidone and quetiapine. Ziprasidone and aripiprazole are thought to have the smallest effects on weight and insulin resistance, but clinical experience with these newer agents is not as developed as that with the older agents.

The issue of metabolic side effects such as hyperglycemia with these medications is somewhat clouded by the fact that drug-naïve schizophrenics also appear to have an increased incidence of impaired glucose metabolism. The question is whether the increased risk for diabetes and hyperglycemia is a function of the disease state of schizophrenia, or whether these metabolic effects are the result of adverse medication side effects. It is probably an interaction involving both of these factors that is responsible for the observations of increased adverse metabolic events in patients taking atypical antipsychotics.

Atypical antipsychotic medications

- Clozapine (Clozaril®) (FDA-approval: 1990) Available only in oral tablets.

Risperidone (Risperdal®) (FDA-approval: 1993) Available in oral tablets, dissolving tablets, liquid form, and extended release intramusclar injection.

Olanzapine (Zyprexa®) (FDA-approval: 1996) Available in oral tablets, dissolving tablets, and intramuscular injection.
Quetiapine (Seroquel®) (FDA-approval: 1997) Available only in oral tablets.
Ziprasidone (Geodon®) (FDA-approval: 2001) Available in oral capsules and intramuscular injection.
Aripiprazole (Abilify®) (FDA)-approval: 2002) Available in oral tablets and dissolving tablets.
Sertindole (Serlect®, Serdolect®) (Not approved by the FDA for use in the USA).
Zotepine (Not approved by the FDA for use in the USA).
Amisulpride (Not approved by the FDA for use in the USA).

Olanzapine (Zyprexa)

Olanzapine (oh-LAN-za-peen, sold as *Zyprexa*®, *Zydis*®, or in combination with fluoxetine, as *Symbyax*®) was the third atypical antipsychotic to gain approval by the Food and Drug Administration (FDA) and has become one of the most commonly used atypical antipsychotics. Olanzapine has been approved by the FDA for the treatment of schizophrenia, acute mania in bipolar disorder, agitation associated with schizophrenia and bipolar disorder, and as maintenance treatment in bipolar disorder and psychotic depression.

It has also been established in treating depression off-label because of its mood-stabilizing properties and its ability to increase the efficacy of antidepressants. Olanzapine is manufactured and marketed by the pharmaceutical company Eli Lilly and Company. It is available as a pill that comes in the strengths of 2.5 mg, 5 mg, 7.5 mg, 10 mg, 15 mg, and 20 mg and as as Zydis orally disintegrating tablets in the strengths of 5 mg, 10 mg, 15 mg, and 20 mg. It is also available as a rapid-acting intramuscular injection for short term acute use.

Case-reports, open-label, and small pilot studies suggest efficacy of olanzapine for the treatment of some anxiety spectrum disorders (e.g. general anxiety disorder, panic disorder, post-traumatic stress disorder); however, olanzapine has not been rigorously evaluated in randomized, placebo-controlled trials for this use and is not FDA approved for these indications. Other common off-label uses of olanzapine include the treatment of eating disorders (e.g. anorexia nervosa) and as an adjunctive treatment for major depressive disorder with psychotic features.

Pharmacology

Olanzapine is structurally similar to clozapine, and is classified as a thienobenzodiazepine. Olanzapine has a high affinity for dopamine and serotonin receptors. Like most atypical antipsychotics compared to the older typical ones, Olanzapine has a lower affinity for histamine, cholinergic muscarinic and alpha adrenergic receptors. The mechanism of action of olanzapine is unknown, however it is theorized that olanzapine's antipsychotic activity is mediated primarily by antagonism at dopamine receptors(does not allow dopamine to activate the dopamine receptors), specifically D2. Serotonin antagonism may also play a role in the effectiveness of olanzapine, but the significance of 5-HT2A antagonism is debated among researchers. Antagonism at muscarinic, histaminic and alpha adrenergic receptors likely explains some of the side effects of olanzapine, such as anticholinergic effects, weight gain, sedation and orthostatic hypotension.

Pharmacokinetics

Olanzapine displays linear kinetics. Its elimination half-life ranges from 21 to 54 hours. Steady state plasma concentrations are achieved in about a week. Olanzapine undergoes extensive first pass metabolism and bioavailability is not affected by food.

Metabolism

Olanzapine is metabolized by the Cytochrome P450 system isoenzymes 1A2 and 2D6 (minor pathway). Drug metabolism may be increased or decreased by agents that induce (e.g. cigarette smoke) or inhibit (e.g. fluvoxamine or ciprofloxacin) CYP1A2 activity respectively.

Adverse events

Adverse events reported in the package insert for olanzapine include dry mouth, dizziness, sedation, insomnia, orthostatic hypotension and akathisia. Olanzapine is reported to cause extrapyramidal symptoms, tardive dyskinesia and neuroleptic malignant syndrome, although at a much reduced rate when compared to the classical anti-psychotics.

Recently the FDA required the manufacturers of all atypical antipsychotics to include a warning about the risk of hyperglycemia and diabetes with atypical antipsychotics. Additionally there are some case reports of olanzapine-induced diabetic ketoacidosis. There is data showing that olanzapine can decrease insulin sensitivity. In addition, increased triglyceride levels may also be an issue with olanzapine. Impaired glucose metabolism, high triglycerides, and obesity have been shown to be constituents of the metabolic syndrome and may increase the risk of cardiovascular disease. The data suggests that olanzapine may be more likely to cause adverse metabolic effects than some of the other atypical antipsychotics.

Citing an increased risk of stroke, in 2004 the Committee for the Safety of Medicines (CSM) in the UK issued a warning that olanzapine and risperidone, both atypical antipsychotic medications, should not be given to elderly patients with dementia.

The results of a large, random-design study funded by NIH's National Institute of Mental Health (NIMH) were published in September 2005. The 18-month study, which involved 1,400 participants at 57 sites around the country, found that "patients on olanzapine also experienced substantially more weight gain and metabolic changes associated with an increased risk of diabetes than those participants taking the other drugs." [1]

Data from a small, open-label, non-randomized study seems to suggest that taking olanzapine by orally dissolving tablets may not be associated with the same degree of weight gain as conventional tablet formulations (de Haan, et al. Psychopharmacology 2004 Sep;175(3):389-90); however this has not been substantiated in a blinded experimental setting.

According to information made available from the U.S. National Library of Medicine the effects of olanzapine on children under the age of eighteen have not been thoroughly researched. Additionally, it is not clearly understood what effect, if any, olanzapine might

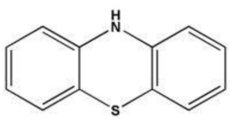
have on the unborn child of a mother who is being treated with the drug. Laboratory tests have shown that olanzapine can penetrate the placenta in animals. It is also unknown whether or not olanzapine is transferable in human breast-milk. Olanzapine does, however, pass in the breast-milk of laboratory animals.

The effects of olanzapine, in conjunction with other drugs has not been fully studied. Alcohol and any other centrally acting drugs should be avoided while taking olanzapine.

Overdose

Symptoms of an overdose include tachycardia, agitation, dysarthria, decreased consciousness and coma. Death has been reported after an acute overdose of 450mg, but also survival after an acute overdose of 1500mg.

Phenothiazines



Systematic name 10H-phenothiazine

Other names thiodiphenylamine, dibenzothiazine

Molecular formula $C_{12}H_9NS$

Molar mass 199.2762 g/mol

Appearance yellow rhombic leaflets or diamond-shaped plates

CAS number 92-84-2

Properties

Density and phase: solid at STP

Soluble benzene, ether, hot acetic acid, ethanol (slightly), mineral oil (slightly)

Insoluble water, petroleum ether, chloroform

Melting point 185 °C

Boiling point 371 °C

Acidity (pK_a) approx 23 in DMSO

Except where noted otherwise, data are given for materials in their standard state (at 25 °C, 100 kPa)

Phenothiazine (a phenol derivative of thiazine) is a pesticide and industrial chemical used in pharmaceutical manufacturing. It is sometimes used as an antihelminthic. It was introduced by DuPont as an insecticide in 1935. It is now most commonly used as an intermediate chemical in the manufacture of various psychiatric drugs.

Phenothiazine-derivative drugs

The word "phenothiazines" is used to describe the largest of the five main classes of antipsychotic drugs. Although these drugs are generally effective, there are often serious side effects including tardive dyskinesia and sedation (especially in the early stages of treatment).

There are three groups of phenothiazines, differing by their chemical structure and their pharmacological effects:

Group	Autonomic	Example	Sedative	Extrapyramidal side-effect
Aliphatic compounds	moderate	Chlorpromazine (Thorazine, Largactil)	strong	moderate
		Promazine	moderate	moderate
		Triflupromazine (Vesprin)	strong	moderate/strong
		Levomepromazine (Nozinan)	extremely strong	low
Piperidines	strong	Mesoridazine	strong	weak
		Thioridazine (Mellaril)	strong	weak
Piperazines	weak	Fluphenazine	weak/moderate	strong
		Perphenazine	weak/moderate	strong
		Prochlorperazine (Compazine, Stemetil)		
		Trifluoperazine (Stelazine)	moderate	strong

Tardive dyskinesia is a serious neurological disorder caused by the long-term and/or high-dose use of dopamine antagonists, usually antipsychotics and among them especially the typical antipsychotics. These neuroleptic drugs are generally prescribed for serious psychiatric disorders. The older typical antipsychotics, which appear to cause tardive dyskinesia somewhat more often than the newer atypical antipsychotics, are being prescribed less frequently. There are some new uses, however, such as year-long implants that are being developed using the older typicals, e.g., Haldol®, one of the worst offenders when it comes to tardive dyskinesia. Other dopamine antagonists that can cause tardive dyskinesia are drugs for gastrointestinal disorders (for example metoclopramide) and neurological disorders. Some drugs that are not intended to affect dopamine, such as SSRI antidepressants, may also cause tardive dyskinesia. Newer atypical antipsychotics such as olanzapine and risperidone appear to cause tardive dyskinesia somewhat less frequently.

The term *tardive dyskinesia* was introduced in 1964. Dyskinesia means "abnormal movement" and tardive means "late", signifying that the dyskinesia only occurs after some time has elapsed following initial administration of the neuroleptic drug.

Features

Tardive dyskinesia is characterized by repetitive, involuntary, purposeless movements. Features of the disorder may include grimacing, tongue protrusion, lip smacking, puckering and pursing of the lips, and rapid eye blinking. Rapid movements of the arms, legs, and trunk may also occur. Impaired movements of the fingers may appear as though the patient is playing an invisible guitar or piano. Tardive dyskinesia, like Tourette Syndrome, can be considered an 'opposite' of Parkinson's disease. Patients with Parkinson's disease have difficulty moving, while patients with tardive dyskinesia have difficulty NOT moving.

Other closely related neurological disorders have been recognized as variants of tardive dyskinesia. Tardive akathisia involves painful feelings of inner tension and anxiety and a compulsive drive to move the body. In the extreme, the individual undergoes internal torture

and can no longer sit still. Tardive tourettism is a tic disorder that can closely mimic Tourette Syndrome, sometimes to the point where the two can only be distinguished by the details of their onsets.

Cause

The cause of tardive dyskinesia appears to be related to damage to the system that uses and processes the neurotransmitter dopamine. It is thought that postsynaptic dopaminergic receptors become supersensitive to stimulation as a result of the use of neuroleptic drugs and that this supersensitivity causes the symptoms of tardive dyskinesia. The available research seems to suggest that the concurrent prophylactic use of a neuroleptic and an antiparkinsonian drug is useless to avoid early extrapyramidal side-effects and may render the patient more sensitive to tardive dyskinesia. Since 1973 the use of these drugs have been found to be associated with the development of tardive dyskinesia (Crane, 1973). Since some of the symptoms of tardive dyskinesia can be interpreted as schizophrenia by doctors, they may prescribe additional neuroleptic drugs to treat it, leading to increased risk of more prevalent tardive dyskinesia. Several studies have indicated that long-term neuroleptic use is associated with both cognitive deterioration and atrophy of the brain (Breggin, 1990; Gualtieri and Barnhill, 1988).

Treatment

Primary prevention of tardive dyskinesia is achieved by using the lowest effective dose of a neuroleptic for the shortest time. If tardive dyskinesia is diagnosed, the causative drug should be reduced or discontinued if possible. Tardive dyskinesia may persist after withdrawal of the drug for months, years, or even permanently. There is no known cure for tardive dyskinesia, but preliminary research suggests that the atypical neuroleptic clozapine (Clozaril®) may improve the state of the patient. Improvements are also seen in some cases, if the high potency benzodiazepines - lorazepam (Ativan®), diazepam (Valium®), or clonazepam (Klonopin®)--are used. The findings about the effects of natural substances, such as vitamin E (Alpha-Tocopherol) or melatonin, are inconclusive. Treatment with adrenergic blocking agents and dopamine agonists like bromocriptine also remains somewhat controversial. There have been some reports of promising effects from the drug tetrabenazine (a different kind of neuroleptic). On the contrary, most antiparkinsonian drugs worsen the state of the patient.

Caveats

Natural remedies are unproven, since they are seldom tested in a controlled setting such as a drug trial. Preliminary research indicates that alternating rest, and regular exercise also negate the symptoms of tardive dyskinesia, necessary for all mental health outpatients who must maintain anti-psychotic neuroleptic drug regimes, for on-going 'wellness'. Switching to a newer drug with less side-effects, might be an option - in a controlled / monitored environment.

Epidemiology

Tardive dyskinesia most commonly occurs in patients with psychiatric conditions who are treated with antipsychotic medications for many years. Some estimates suggest that it occurs in 15-30% of patients receiving treatment with antipsychotic neuroleptic medications for 3 months or longer. Other estimates suggest that with each year of neuroleptic use, 5% of the patients will show signs of tardive dyskinesia, i.e., 5% after one year, 10% after two years, 15% after three years with no clear upper limit. Eventually, according to these estimates, if on the drugs long enough, the majority of patients will develop the disorder.[2] The incidence of tardive dyskinesia varies with the type of neuroleptic (e.g., haloperidol (Haldol®) more often than perphenazine (Trilafon®)), daily dose and duration of treatment (the higher the daily dose and the longer the duration of treatment, the higher the risk).

The elderly and female patients are more prone to develop tardive dyskinesia. Cigarette smokers also have a higher prevalence of tardive dyskinesia. Children and adolescents are much more sensitive to the early and late extrapyramidal side-effects of neuroleptics than adults. Because of this, treatment of youngsters with neuroleptics may be contraindicated, and many authorities believe that they should be initiated only as a last resort, using the lowest dose regime possible and the shortest duration of treatment in accordance with good patient management.

Tardive dyskinesia can become a thoroughly debilitating social handicap. Some believe the devastating impact of tardive dyskinesia illustrates why patients and/or their families (guardians and/or caregivers/nurses) should receive full information about the neuroleptic before starting treatment (informed consent).

Typical antipsychotics

Typical antipsychotics (sometimes referred to as *conventional antipsychotics*, *classical neuroleptics* or *major tranquilizers*) are a class of antipsychotic drugs first developed in the 1950s and used to treat psychosis (in particular, schizophrenia), and are generally being replaced by atypical antipsychotic drugs. Typical antipsychotics may also be used for the treatment of acute mania, agitation, and other conditions.

Traditional antipsychotics are broken down into low-potency and high-potency classifications. Fluphenazine and haloperidol are examples of high-potency typical antipsychotics, and chlorpromazine is an example of a low potency antipsychotic. High-potency typical antipsychotics tend to be associated with more extrapyramidal side effects (EPS) and less histaminic (e.g. sedation), alpha adrenergic (e.g. orthostasis) and anticholinergic (e.g. dry mouth) side effects, while low-potency typical antipsychotics tend to be associated with less EPS but more H1, alpha1, and muscarinic side effects.

Depot injections

Some of the high-potency antipsychotics, particularly haloperidol and fluphenazine, have been formulated as the decanoate ester (e.g. fluphenazine decanoate) to allow for a slow release of the active drug when given as a deep, intramuscular injection. This has the advantage of providing reliable dosing for a person who has trouble with compliance. Depot injections can also be used for involuntary community treatment patients to ensure compliance with a community treatment order when the patient would refuse to take daily oral medication. For practical reasons, depot preparations are limited to high-potency antipsychotics so the treating physician has a limited choice. It is therefore preferable to use oral medications if the cooperation and compliance of the patient can be obtained.

Common side effects

Side effects vary among the various agents in this class of medications, but common side effects include: dry mouth, muscle stiffness, muscle cramping, tremors, EPS and weight-gain. EPS is a cluster of symptoms consisting of parkinsonism, dystonias, and akathisia. Anticholinergics such as benztropine and diphenhydramine are commonly prescribed to treat the symptoms of EPS.

Risks of serious side effects

There is a significant risk of the serious condition tardive dyskinesia developing as a side effect of typical antipsychotics. The risk of developing tardive dyskinesia after chronic typical antipsychotic usage varies on several factors, such as age and gender. The commonly reported incidence of TD among younger patients is about 5% per year. Among older patients incidence rates as high than 20% per year have been reported. The average prevalence is approximately 30%. There are no treatments that have consistently been

shown to be effective for the treatment of tardive dyskinesias, however branched chain amino acids, melatonin, and vitamin E have been suggested as possible treatments. The atypical antipsychotic clozapine has also been suggested as an alternative antipsychotic for patients experiencing tardive dyskinesia. Tardive dyskinesia may reverse upon discontinuation of the offending agent or it may be irreversible.

Neuroleptic malignant syndrome, or NMS, is a rare, but potentially fatal side effect of antipsychotic treatment. NMS is characterized by fever, muscle rigidity, autonomic dysfunction, and altered mental status. Treatment includes discontinuation of the offending agent and supportive care.

The role of typical antipsychotics has come into question recently as studies have suggested that atypical antipsychotics may increase the risk of death in elderly patients. A retrospective cohort study from the New England Journal of Medicine on Dec. 1, 2005 showed an increase in risk of death with the use of typical antipsychotics that was on par with the increase shown with atypical antipsychotics. This has led some to question the common use of antipsychotics for the treatment of agitation in the elderly, particularly with the availability of alternatives such as mood stabilizing and antiepileptic drugs.

Haloperidol (sold under the tradenames *Aloperidin*, *Bioperidolo*, *Brotopon*, *Dozic*, *Duraperidol* (Germany), *Einalon S*, *Eukystol*, *Haldol*, *Halosten*, *Keselan*, *Linton*, *Peluces*, *Serenace*, *Serenase*, *Sigaperidol*) is a conventional butyrophenone antipsychotic drug. It was developed in 1957 by the Belgian company Janssen Pharmaceutica and submitted to first clinical trials in Belgium in the same year. After being rejected by U.S. company Searle due to side effects, it was later marketed in the U.S. by McNeil Laboratories.

Chemistry

Haloperidol is an odourless white to yellow crystalline powder. Its chemical name is 4-[4-(p-chlorophenyl)-4-hydroxypiperidino]-4'-fluorobutyrophenone and its empirical formula is $C_{21}H_{23}ClFNO_2$

Pharmacology

Haloperidol is a neuroleptic and a butyrophenone. Due to its strong central antidopaminergic action, it is classified as a highly potent neuroleptic. It is approximately 50 times more potent than chlorpromazine on a weight basis (50mg chlorpromazine are equivalent to 1mg haloperidol). Haloperidol possesses a strong activity against delusions and hallucinations, most likely due to an effective dopaminergic receptor blockage in the mesocortex and the limbic system of the brain. It blocks the dopaminergic action in the nigrostriatal pathways, which is the probable reason for the high frequency of extrapyramidal-motoric side-effects (dystonias, akathisia, pseudoparkinsonism). It has minor antihistaminic and anticholinergic properties, therefore cardiovascular and anticholinergic side-effects such as hypotension, dry mouth, constipation, etc., are seen quite infrequently, compared with less potent neuroleptics such as chlorpromazine. Haloperidol also has sedative properties and displays a strong action against psychomotor agitation, due to a specific action in the limbic system. It therefore is an effective treatment for mania and states of agitation. Additionally, it can be given as an adjuvant in the therapy of severe chronic pain.

The peripheral antidopaminergic effects of haloperidol account for its strong antiemetic activity. There, it acts at the CTZ (Chemical Trigger Zone). Haloperidol is useful to treat severe forms of nausea/emesis such as those resulting from chemotherapy. The peripheral effects lead also to a relaxation of the gastric sphincter muscle and an increased release of the hormone prolactin, with the possible emergence of breast enlargement and secretion of milk (lactation) in both sexes.

Pharmacokinetics

Oral dosing

Haloperidol is well absorbed after oral dosing. There is a first pass metabolism leading to a reduced oral bioavailability of the drug (60 to 70%). Peak plasma-levels are observed after 3 to 6 hours.

Intramuscular injections

The drug is well and rapidly absorbed and has a high bioavailability. Plasma-levels reach their maximum within 20 minutes after injection.

Intravenous injections

The bioavailability is 100% and the very rapid onset of action is seen within about ten minutes. The duration of action is 3 to 6 hours. If haloperidol is given as slow IV infusion, the onset of action is retarded, but the duration prolonged compared to IV injection.

Therapeutic concentrations

Plasma levels of 4 micrograms per liter to 20 (up to 25) micrograms per liter are required for therapeutic action. The determination of plasma levels can be used to decide about dose adjustments and to check compliance, particular in long-term patients. Plasma levels in excess of the therapeutic range may lead to a higher incidence of side-effects or even pose the risk of haloperidol intoxication.

Uses

Haloperidol is used in the control of the symptoms of:

- Acute psychosis, such as drug psychosis (LSD, amphetamines, PCP), psychosis associated with high fever or metabolic disease
- Acute and chronic schizophrenia
- Acute manic phases until the concomitantly given first-line drugs such as lithium or valproate are effective
- Hyperactivity, aggression
- Acute delirium
- Otherwise uncontrollable severe behavioral disorders in children and adolescents
- Agitation and confusion associated with cerebral sclerosis
- Adjunctive treatment of alcohol and opioid withdrawal
- Treatment of neurological disorders such as tics, Tourette syndrome, and chorea
- Treatment of severe nausea/emesis (postoperative, side-effects of radiation and cancer chemotherapy)
- Adjunctive treatment of severe chronic pain, always together with analgesics
- Therapeutic trial in personality disorders such as borderline personality disorders

Some weeks or even months of treatment may be needed before a remission of schizophrenia is evident.

In some clinics the use of atypical neuroleptics (e.g. clozapine, risperidone, olanzapine, ziprasidone) is generally preferred over haloperidol, because these drugs have an

appreciably lower incidence of extrapyramidal side-effects. Each of these drugs, however, has its own spectrum of potentially serious side-effects (e.g. agranulocytosis with clozapine, weight gain with increased risk of diabetes and of stroke). Atypical neuroleptics are also much more expensive and have recently been the subject of increasing controversy regarding their efficacy in comparison to older products and side effects.

Haloperidol is considered indispensable for treating psychiatric emergency situations. It is enrolled in the World Health Organization "List of Essential Medicines".

As is common with typical neuroleptics, haloperidol is by far more active against "positive" psychotic symptoms (delusions, hallucinations etc.) than against "negative" symptoms (social withdrawal, autism etc.). The effectiveness of haloperidol against positive symptoms has not been outperformed by newer antipsychotics.

Contraindications

Absolute

- Preexisting coma
- Severe intoxication with alcohol or other central depressant drugs
- Known allergy against haloperidol or other butyrophenones or other drug ingredients

Special caution needed

- **Preexisting** Parkinson's disease

- Patients at special risk for the development of QT-Time-Prolongation (hypokalema, concomittant use of other drugs causing the QT-Syndrome)
- Compromised liver-function (as haloperidol is metabolized and eliminated mainly by the liver, dose reductions and/or spaced intervalls may be needed)
- Haloperidol may decrease the seizure-threshold. Treat patients with epilepsy and those with risk factors for the development of seizures (alcohol withdrawal, encephalopathy) with caution. Maintain existing anticonvulsive therapy.
- Patients with hyperthyreosis; the action of haloperidol is intensified and side-effcts are more likely. Initiate an effective therapy of hyperthyreosis.
- IV injections: inject slowly to avoid hypotension or orthostatic collapse. Avoid IV injections in cardiovascular unstable patients (preexisting hypotension, shock, concomitant antihypertensive therapy, heart insufficience). Prefer in these cases moderate oral or IM doses.

Side-effects

The drug is noted for its strong early and late extrapyramidal side-effects. The risk of tardive dyskinesia is around 4% per year in younger patients, higher than with most other antipsychotic drugs. In patients over the age of 45, the percentage of those afflicted can be even higher. Other predispositive factors may be female gender, prexisting affective disorder and cerebral dysfunction.

Other side effects include dry mouth, lethargy, muscle-stiffness, muscle-cramping, restlessness, tremors, and weight-gain; side effects like these are more likely to occur when the drug is given in high doses and/or during long-term treatment. Depression, severe enough to result in suicide, is quite often seen during long-term treatment. Care should be taken to detect and treat depression early in course. Sometimes the change from haloperidol to a mildly potent neuroleptic (e.g. chlorprothixene or chlorpromazine), together with appropriate antidepressant therapy, does help. Sedative and anticholinergic side-effects occur more frequently in the elderly.

Neuroleptic malignant syndrome (NMS) is a significant possible side effect. Haloperidol and fluphenazine are the two drugs which cause NMS most often. Allergic and toxic side-effects are uncommon. Skin rash and photosensitivity both occur in less than 1% of patients.

Children and adolescents are particularly sensitive to the early and late extrapyramidal side-effects of haloperidol. It is recommended to treat pediatric patients only if clearly needed and if the psychiatric or neurologic disorder is substantial.

QT prolongation with sudden death is rarely seen. Likewise, the development of thromboembolic complications are also rare.

Haloperidol has a negative impact on vigilance and decreases the ability of the patient to drive or operate a machine, particularly initially.

Abuse and dependence

Haloperidol is completely devoid of any potential psychological dependence.

Unpleasant withdrawal symptoms, if haloperidol is stopped abruptly after long-term treatment, are commonly noted. These are usually agitation, anxiety, insomnia, and nausea. Rebound of psychotic symptoms and mood swing into mania are also seen. These symptoms are not indicative of dependence. Instead of terminating treatment with haloperidol abruptly, decrease its dose, if possible, by 20 to 25% weekly. If haloperidol has to be stopped at once for medical reasons, give tranquilizers like Diazepam or Alprazolam for a few weeks, as needed, for effective alleviation of withdrawal symptoms.

Other Remarks

During long-term treatment of chronic psychiatric disorders, it should be tried - in regular intervals - to reduce the daily dose to the lowest level needed for maintenance of remission. Sometimes, it may be indicated to terminate haloperidol treatment gradually.

Other forms of therapy (psychotherapy, occupational therapy/ergotherapie, social rehabilitation) should be instituted properly.

Pregnancy and lactation

Data from animal experiments indicate haloperidol is not teratogenic, but is embryotoxic in high doses. In humans, no controlled studies exist. Unconfirmed studies in pregnant women revealed possible damage to the fetus, although most of the women were exposed to multiple drugs during pregnancy. Following accepted general principles, haloperidol should only be given during pregnancy if the benefit to the mother clearly outweighs the potential fetal risk.

Haloperidol, when given to lactating women, is found in significant amounts in their milk. Breastfed children sometimes show extrapyramidal symptoms. If the use of haloperidol during lactation seems indicated, the benefit for the mother should clearly outweigh the risk for the child. Consider termination of breastfeeding.

Carcinogenicity

So far, no statistically acceptable evidence is found to associate long-term use of haloperidol with the potential for increased breast cancer risk in female patients. In an unconfirmed study, relative risks of breast cancer, in inmates of the Buffalo Psychiatric Center undergoing long-term treatment with haloperidol, were 3.5 (compared to patients hospitalized in general or internal medicine facilities) and 9.5 (general population), respectively (authors: U. Halbreich et al, loc. cit.: 'American Journal of Psychiatry', 1996). These results need confirmation by larger studies. If true, carcinogenity is most probably related to the strong increase in plasma-levels of prolactin under long-term treatment with haloperidol. This news is another good reason to avoid any unnecessary use of haloperidol.

Interactions

- Other cental depressants (alcohol, tranquilizers, narcotics): actions and side-effects of these drugs (sedation, respiratory depression) are increased. In particular, the doses of concomitantly used opioids for chronic pain can be reduced by 50%.

Methyldopa: increased risk of extrapyramidal side-effects and other unwanted central effects

Levodopa: decreased action of levodopa

Tricyclic antidepressants: metabolism and elimination of tricyclics significantly decreased, increased toxicity noted (anticholinergic and cardiovascular side-effcts, lowering of seizure-threshold)

Quinidine, buspirone, and fluoxetine: increased plasma-levels of haloperidol, decrease haloperidol dose, if necessary

Carbamazepine, phenobarbital, and rifampicin: plasma-levels of haloperidol significantly decreased, increase haloperidol dose, if necessary.

lithium: rare cases of the following symptoms have been noted: encephalopathy, early and late extrapyramidal side-effects, other neurologic symptoms and coma. Check lithium plasma levels regularly and keep the dose of haloperidol as low as possible.

Guanethidine: antihypertensive action antagonized

Epinephrine: action antagonized, paradoxical decrease in blood pressure may result

Doses

As directed by the physician, depends on the condition to be treated, age and weight of patient:

- Acute problems: single doses of 1 mg to 5 mg (up to 10mg) oral or i.m, usually repeated every 4 to 8 hours. Do not exceed an oral dose of 100 mg daily. Doses used for IV injection are usually 5 to 10 mg as a single dose; not exceeding 50 mg daily.
- Chronic conditions: 0.5 to 20 mg daily oral, rarely more. The lowest dose that maintains remission should by employeed.
- Experimental doses: In resistant cases of psychosis small studies with oral doses of up to 300 mg daily have been conducted (in most cases together with an anticholinergic antiparkinsonian drug (Biperiden, Benzatropine etc.) to avoid severe early extrapyramidal side-effects. These studies showed no superior results and led to severe side-effcts, also the frequency of otherwise unusual side-effects (hypotension, QT-time prolongation, and serious cardiac arrhythmias) was dramatically increased. The clinical use of haloperidol in these doses is discouraged now and it is recommended to switch the patient gradually to a different neuroleptic (e.g. clozapine, olanzapine, aripiprazole).

Depot forms are also available, these are injected deeply i.m. at regular intervalls. The depot forms are not suitable for initial treatment.

Overdose

Experimental evidence from animal studies indicates that doses needed for acute poisoning are quite high in relation to therapeutic doses.

Symptoms are usually due to exaggerated side-effects. Most often encountered are:

- Severe extrapyramidal side-effects with muscle rigidity and tremors, akathisia etc. (inject 5 mg biperiden (Akineton®) slowly IV, repeat after some hours if necessary). Sometimes oral or IM treatment with biperiden is needed for several days or even weeks. If the patient is very upset about extrapyramidal side-effects, small doses of lorazepam (0.5 to 1 mg orally, repeated every 4 to 6 hours if necessary) can be given. Lorazepam has an intrinsic action against upset, anxiety, and extrapyramidal side-effects.
- Hypotension or hypertension
- Sedation
- Anticholinergic side-effects (dry mouth, constipation, paralytic ileus, difficulties in urinating, massive sweating). Cautious doses of physostigmine may be given repeatedly. *N.B. Physostigmine may increase the risk of seizures!*
- Coma in severe cases, accompanied by respiratory depression and massive hypotension, shock

- Rarely serious ventricular arrhythmia (torsades de pointes) with or without prolonged QT-time
- Epileptic seizures, give careful doses of diazepam 5 mg to 10 mg by slow IV injection, repeatedly if needed, until seizures subside. Take care not to worsen central depression or respiratory depression caused by haloperidol. The treatment facility should be able to institute artificial respiration readily. Valproate first given as slow IV infusion and later orally may also be effective.

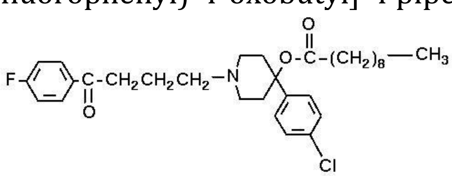
Treatment is merely symptomatic and involves intensive care with stabilization of vital functions. In early detected cases of oral overdose induction of emesis, gastric lavage and the use of activated charcoal can all be tried. Avoid epinephrine for treatment of hypotension and shock, because its action might be reversed.

Generally, the prognosis of overdose is good and lasting damage is not known, provided that the patient has survived the initial phase.

Overdoses with depot injections are uncommon, because almost always experienced personnel administer them to patients.

Other formulations

As well as haloperidol, the decanoate ester haloperidol decanoate (*Haldol decanoate*®, *Halomonth*®, *Neoperidole*®) can be used or haloperidol Lactate. The decanoate has a greatly extended duration of effect and its structural formula is 4-(4-chlorophenyl)-1-1[4-(4-fluorophenyl)-4-oxobutyl]-4 piperidinyl decanoate (see image below).



Veterinary use

Haloperidol is also used on many different kinds of animals. It appears to be particularly successful when given to birds; e.g. a parrot that will not otherwise stop plucking its feathers out.

Dose forms

- Liquid: 2 mg/mL, also 10 mg/mL
- Tablets: 0,5 mg, 1 mg, 2 mg, 5 mg, 10 mg, 20 mg
- Injection: 5 mg (1 mL)
- Depot injection forms
- The original drug Haldol® and many generics are available

Lithium pharmacology

Lithium in pharmacology refers to the lithium ion, Li+, used as a drug. Lithium is administered in a number of chemical salts of lithium, which are used primarily in the treatment of bipolar disorder as mood stabilizing drugs. They are also sometimes used to treat depression and mania. Lithium carbonate (Li_2CO_3), sold as Carbolith®, Cibalith-S®, Duralith®, Eskalith®, Lithane®, Lithizine®, Lithobid®, Lithonate®, Lithotabs® and Maniprex®, is the most commonly prescribed, whilst the citrate salt lithium citrate ($Li_3C_6H_5O_7$), the sulfate salt lithium sulfate (Li_2SO_4), aspartate and the orotate salt lithium orotate are alternatives.

Lithium is widely distributed in the central nervous system and interacts with a number of neurotransmitters and receptors, decreasing noradrenaline release and increasing serotonin synthesis.

History

Solutions of lithium will dissolve uric acid crystals. Against the background of nineteenth century theories linking excess uric acid to a range of disorders, including manic disorders, Carl Lange in Denmark and William Hammond in New York used lithium to treat mania from the 1870s onwards.

However, by the turn of the century, the use of lithium in this way died out and was seemingly forgotten. The use of lithium salts to treat mania was rediscovered by the Australian psychiatrist John Cade in 1949, after he discovered the effect of first lithium urate, and then other lithium salts, on animals. Cade had actually been trying to test the effects of urate as a control for chemicals in urine, and used the lithium salt because it was the most soluble; the animals were tranquilized and Cade eventually tracked the effect down to the lithium itself. Cade proposed lithium as a tranquilizer, and soon succeeded in controlling mania in chronically hospitalized patients. This was one of the first successful applications of a drug to treat mental illness (perhaps the first, if herbal-source drugs like Rauwolfia are discounted), and it opened the door for the development of medicines for other mental problems in the next decades.

The rest of the world was slow to adopt this revolutionary treatment, largely because of deaths which resulted from even relatively minor overdosing, and from use of lithium chloride as a substitute for table salt. Largely through the research and other efforts of Denmark's Mogens Schou in Europe, and Samuel Gershon in the U.S., this resistance was

slowly overcome. The application of lithium for manic illness was approved by the United States Food and Drug Administration in 1970.

Treatment

Lithium treatment is used to treat mania in bipolar disorder. Initially, lithium is often used in conjunction with antipsychotic drugs as it can take up to a week for lithium to have an effect. Lithium is also used as prophylaxis for depression and mania in bipolar disorder. Also, it is sometimes used for other disorders, like cycloid psychosis, unipolar depression, migraine and others. It is sometimes used as an "augmenting" agent, to increase the benefits of standard drugs used for unipolar depression. Lithium treatment was previously considered to be unsuitable for children, however more recent studies show its effectiveness for treatment of early-onset bipolar disorder in children as young as four.

Mechanism of Action

The precise mechanism of action of Li+ as a mood-stabilizing agent is currently unknown. It is possible that Li+ produces its effects by interacting with the transport of monovalent or divalent cations in neurons. However, because it is a poor substrate at the sodium pump, it cannot maintain a membrane potential and only sustains a small gradient across biological membranes. Yet Li+ is similar enough to Na+ in that under experimental conditions, Li+ can replace Na+ for production of a single action potential in neurons.

Recent research suggests three different mechanisms which may act together to deliver the mood-stabilizing effect of this ion (Jope RS, Mol Psychiatry 1999 Mar; 4(2):117-28). An increasing number of scientists have come to the conclusion that the excitatory neurotransmitter glutamate is the key factor in understanding how lithium works. Other mood stabilizers such as valproate and lamotrigine exert influence over glutamate, suggesting a possible biological explanation for mania. The other mechanisms by which lithium might help to regulate mood include the alteration of gene expression and the non-competitive inhibition of an enzyme called inositol monophosphatase.

Unlike other psychoactive drugs, Li+ produces no obvious psychotropic effects, (such as euphoria) in normal individuals at therapeutic concentrations.

Dr. Klein and his colleagues' at the University of Pennsylvania discovered in 1996 that lithium ion deactivates the GSK-3B enzyme [1]. The regulation of GSK-3B by lithium may affect the circadian clock -- and recent research (Feb 2006) seems to concur with this conclusion. When the GSK-3B is activated, the protein Bmal1 is unable to reset the "master clock" inside the brain which disrupts the body's natural cycle. When the cycle is disrupted, the routine schedules of many functions (metabolism, sleep, body temperature) are disturbed. Lithium may thus restore disruption of a normal brain function in some people. Its complete mechanism in treatment of mood disorders remains a mystery.

Lithium toxicity and side effects

The required dosage (15-20mg per kg of body weight) is slightly less than the toxic level, requiring blood levels of lithium to be monitored extremely closely during treatment. In

order to prescribe the correct dosage, the patient's entire medical history, both physical and psychological, is taken into consideration. Blood tests are carried out every 3 months to ensure the level of lithium is appropriate and to prevent toxicity, along with kidney and thyroid tests.

Those who use lithium should receive regular (generally monthly once stable) blood tests and should monitor thyroid function annually and kidney function every three to six months for abnormalities. As it interferes with the regulation of sodium and water levels in the body, lithium can cause dehydration. Dehydration, which is compounded by heat, can result in increasing lithium levels.

High doses of haloperidol, fluphenazine, or flupenthixol may be hazardous when used with lithium; irreversible toxic encephalopathy has been reported.

Lithium salts, with the possible exception of lithium orotate, have a narrow therapeutic/toxic ratio and should therefore not be prescribed unless facilities for monitoring plasma concentrations are available. Patients should be carefully selected. Doses are adjusted to achieve plasma concentrations of 0.6 to 1.2mmol Li+/litre (lower end of the range for maintenance therapy and elderly patients, higher end for pediatric patients) on samples taken 12 hours after the preceding dose. Overdosage, usually with plasma concentrations over 1.5mmol Li+/litre, may be fatal and toxic effects include tremor, ataxia, dysarthria, nystagmus, renal impairment, and convulsions. If these potentially hazardous signs occur, treatment should be stopped, plasma lithium concentrations redetermined, and steps taken to reverse lithium toxicity.

Lithium toxicity is compounded by sodium depletion. Concurrent use of diuretics that inhibit the uptake of sodium by the distal tubule (e.g. thiazides) is hazardous and should be avoided. In mild cases withdrawal of lithium and administration of generous amounts of sodium and fluid will reverse the toxicity. Plasma concentrations in excess of 2.5 mmol Li±/litre are usually associated with serious toxicity requiring emergency treatment. When toxic concentrations are reached there may be a delay of 1 or 2 days before maximum toxicity occurs.

In long-term use, therapeutic concentrations of lithium have been thought to cause histological and functional changes in the kidney. The significance of such changes is not clear but is of sufficient concern to discourage long-term use of lithium unless it is definitely indicated. An important consequence is the development of diabetes insipidus (inability to concentrate urine). Patients should therefore be maintained on lithium treatment after 3-5 years only if, on assessment, benefit persists. Conventional and sustained-release tablets are available. Preparations vary widely in bioavailability, and a change in the formulation used requires the same precautions as initiation of treatment. There are few reasons to prefer any one simple salt of lithium; the carbonate has been the more widely used, but the citrate is also available.

Lithium teratogenicity

Though less teratogenic than initially thought, Lithium increases the risk of congenital cardiac abnormalities to ~2% of newborns.

Lithium overdose

Signs that lithium levels within the body are too high include: confusion, diarrhea, lethargy, severe tremors, and/or an upset stomach.

Lithium and culture

As with many other drugs, songs have been written about its effects, "Lithium Sunset" by Sting, "Lithium" by Nirvana, and "Lithium" by Evanescence among others.

The soft drink 7 Up, originally named "Bib-Label Lithiated Lemon-Lime Soda", contained lithium citrate until it was reformulated in 1950.

Hundreds of other soft drinks also included lithium salts or lithia waters as well as at least one brewery which produced Lithia beers (all of these were forced to remove lithium in 1948).

An early version of Coca Cola available in pharmacies' soda fountains called Lithia Coke was a mixture of Coca Cola syrup and lithia water -- lithia waters are naturally occurring mineral waters with higher lithium amounts.

The amount of lithium in any of the commercially available soft drinks was hundreds of times less than a minimum psychiatric dose but the ban didn't make any distinctions on that basis.

Antitussives

A *cough medicine* is a drug used to treat coughing and related conditions. Dry coughs are treated with *cough suppressants* (*antitussives*) that suppress the body's urge to cough, while productive coughs (coughs that produce phlegm) are treated with expectorants that loosen mucus from the respiratory tract. These medicines are widely available in the form of cough syrup, also known as linctus.

Cough suppressants

Cough suppressants may act centrally (on the brain, and specifically the vagus nerve) or locally (on the respiratory tract) to suppress the cough reflex.

Centrally acting suppressants include dextromethorphan (DXM), noscapine, ethyl morphine and codeine.

Peripherally acting substances include local anaesthetics, which reduce the sensation of nerves in the throat, and demulcents, which coat the esophagus. Although it is commonly believed that cough medicines must coat the throat to be effective, there is no evidence that it is possible to control coughing by this means.

One might think it unwise to suppress the cough reflex (the mechanism for expelling mucus from the respiratory tract) but severe coughing may lead to lung irritation, causing a vicious cycle. The cough reflex is also very strong and cannot be completely suppressed. However, dry cough (without mucus production) or cough that is exhausting and preventing sleep should be treated with suppressants.

Recent studies have found that theobromine, a compound found in cocoa, is more effective as a cough suppressant than prescription codeine. This molecule suppresses the "itch" signal from the nerve in the back of the throat that causes the cough reflex. It is possible to get an effective dose from 50g of dark chocolate, which contains 2 to 10 times more cocoa than milk chocolate. Theobromine was also free from side effects in the blind tests.[1]

Expectorants

An expectorant (from Latin ex- "out" + pectoris "of the chest") is a medicine or herb which increases the expulsion of tracheal or bronchial mucus through expectoration or coughing. In over-the-counter preparations, guaifenesin is often used. The effectiveness of expectorants in cough medicines has been questioned; however, water is an effective expectorant and drinking adequate water thins the mucus and enables it to be expelled more easily.[1]

Herbal remedies considered to be expectorants include the following:

- Aniseed (Pimpinella anisum),

Balm of Gilead (Populus gileadensis),
Balsam of Peru (Myroxylon perierae),
Balsam of Tolu (Myroxylon toluifera),
Bloodroot (Sanguinaria canadensis),
Cannabis (Cannabis Sativa),

Cardamom (Elettaria caradamomum),
Coltsfoot (Tussilago farfara),
Comfrey (Symphytum officinale),
Elderflower (Sambucus nigra),
Elecampane (Inula helenium),
Garlic (Allium sativum),
Golden seal (Hydrastis canadensis),
Grindelia (Grindelia camporum),
Hyssop (Hyssopus officinalis),
Iceland moss (Cetraria islandica),
Irish moss (Chondrus crispus),
Liquorice (Glycyrrhiza glabra),
Lobelia (Lobelia inflata),
Lungwort (Sticta pulmonaria),
Marshmallow (Althaea officinalis),
Mouse ear (Hieracium pilosella),
Mullein (Verbascum thapsus),
Pleurisy root (Asclepias tuberosa),
Senega (Polygala senega),
Skunk Cabbage (Symplocarpus foetidus),
Squill (Urginea maritima),
Thuja (Thuja occidentalis),
Thyme (Thymus vulgaris),
Vervain (Verbena officinalis),
White horehound (Marrubium vulgare),
Wild cherry (Prunus serotona).

Cough drops

Cough drops or *throat lozenges* are tablets which people can suck to soothe the throat or to alleviate excessive coughing. They are usually small, sweetened (often with artificial sweeteners), and contain an oral anesthetic, such as menthol, which anesthesizes the receptors in the throat that cause the cough reflex. The occasional use of "lozenge" (first used in 1530, according to the Oxford English Dictionary) is due to the original lozenge shape of cough drops. Popular brands of cough drops include Fisherman's Friend, Halls, Ricola, and Luden's.

Controversy

In 2002, researchers at the University of Bristol (Schroeder & Fahey) published a study in the British Medical Journal indicating that some cough medicines are no more effective than placebos.[2] In 2006, the American College of Chest Physicians published a guideline that had the dual message that many over-the-counter cough medicines are not effective and that those that are effective in treating the symptom do not treat the underlying cause; the underlying disorder emphasized by the guideline was pertussis (whooping cough) in the

elderly.[3] This guideline has been referred to by many news articles in the lay press, which emphasize the economic impact of discouraging cough medicine use while not touching on the health concerns expressed.[4]

Many cough mixtures contain both an expectorant and a suppressant -- even though an expectorant requires the action of a cough to expel mucus. Many believe this supports the idea that cough suppression is just a placebo effect. However, in practice the two active ingredients combine to provide less coughing, but more productive coughs.

Colloquial term usage

"Cough medicine", for example "Grandpa's old cough medicine", is also a commonly used euphemism for whiskey and other strong alcoholic beverages, or even actual cough medicine such as NyQuil which in some formulations has a high alcohol content.

Routes Oral

Dextromethorphan (*DM* or *DXM*) is an antitussive drug that is found in many over-the-counter cold and cough preparations, usually in the form of dextromethorphan hydrobromide. It is also used as a recreational drug.

Chemistry

Dextromethorphan is a salt of the methyl ether dextrorotatory isomer of levorphanol, a narcotic (opioid) analgesic (and DXM itself is an enantiomeric isomer, that is, a mirror image in the 3D space, of levomethorphan, a substance considered an opioid[1]). It is chemically named as 3-methoxy-17-methyl-9(alpha), 13(alpha), 14(alpha)-morphinan hydrobromide monohydrate. DXM occurs as white crystals, is sparingly soluble in water, and freely soluble in alcohol. The drug is dextrorotatory in water (at 20 degrees Celsius, Sodium D-line) with a specific rotation of +27.6 degrees.

Indications

The FDA approved dextromethorphan for over-the-counter sale as a cough suppressant in 1958. This filled the need for a cough suppressant lacking the abuse liability and addictive properties of codeine phosphate, the most widely used cough medication at the time. The advantage of dextromethorphan preparations over those containing codeine (now prescription only in the United States) was the lack of physical addiction potential and

sedative side-effects, although as with most cough supressants, studies show that its effectiveness is highly debatable. See also: Cough medicine controversy

Pharmacodynamics

At therapeutic doses, the drug acts centrally to elevate the threshold for coughing, without inhibiting ciliary activity. Dextromethorphan is rapidly absorbed from the gastrointestinal tract, and exerts its activity within 15 to 60 minutes of ingestion. The duration of action after oral administration is approximately three to eight hours. Because administration of DXM can be accompanied by histamine release, its use in atopic children is very limited.

The average dosage necessary for effective antitussive therapy is between 10mg and 30mg every four to six hours.

According to the WHO committee on Drug Dependence, dextromethorphan, when used recreationally (see non-medical use of dextromethorphan), does not produce physical addiction but can generate slight psychological dependence in some users.

Clinical pharmacology

Following oral administration, dextromethorphan is rapidly absorbed from the gastrointestinal tract, where it enters the bloodstream and crosses the blood-brain barrier. The first-pass through the hepatic portal vein results in some of the drug being metabolized into an active metabolite of dextromethorphan, dextrorphan, the 3-hydroxy derivative of dextromethorphan. The therapeutic activity of dextromethorphan is believed to be caused by both the drug and this metabolite. Dextromethorphan is metabolized by various liver enzymes and subsequently undergoes O-demethylation (producing dextrorphan), N-demethylation, and partial conjugation with glucuronic acid and sulfate ions. Hours after dextromethorphan therapy, (in humans) the metabolites (+)-3-hydroxy-N-methylmorphinan, (+)-3-morphinan, and traces of the unchanged drug are detectable in the urine.

One well known metabolic catalyst involved is a specific cytochrome P450 enzyme known as 2D6, or CYP2D6. A significant portion of the population has a functional deficiency in this enzyme (and are known as poor CYP2D6 metabolizers). As CYP2D6 is the primary metabolic pathway in the inactivation of dextromethorphan, the duration of action and effects of dextromethorphan are significantly increased in such poor metabolizers. Deaths and hospitalizations have been reported in recreational use by poor CYP2D6 metabolizers.

A large number of medications (including antidepressants) are potent inhibitors of CYP2D6 (see CYP2D6 article). There exists, therefore, the potential of drug-drug interactions between dextromethorphan and concomitant medications. There have been reports of fatal consequences arising from such interactions.[2]

Dextromethorphan crosses the blood-brain barrier, and the following pharmacological actions have been reported:

- NMDA glutamatergic receptor antagonist
- Dopamine reuptake inhibitor**[3]**
- Ã1 and Ã2 receptor agonist (Zhou & Musacchio, 1991)

- ±3^{2}4 nicotinic receptor antagonist[4]
- Serotonin reuptake inhibitor[5]

History

Dextromethorphan was first patented with U.S. Patent 2,676,177, and was approved for over-the-counter purchase as an antitussive in 1958.

During the 1960s and 1970s, DXM became available in an over-the-counter tablet form by the brand name Romilar. It was put on the shelves in hopes of cutting down on codeine cough remedies. In 1973, Romilar was taken off the shelves after a burst in sales due to common recreational use. It was then replaced by cough syrup, in an attempt to cut down on recreational usage.

Fibromyalgia treatment

Dextromethorphan is currently being investigated as a potential treatment for fibromyalgia symptoms.

Recreational use

Since their introduction, preparations containing the over-the-counter drug dextromethorphan have been used in a manner inconsistent with their labeling, often as a recreational drug or to induce intoxication (sometimes referred to as "robo-tripping"). Dextromethorphan has little to no psychological effect in the doses used medically, however alteration of consciousness generally occurs following ingestion of approximately 7 to 50 times the therapeutic dose over a relatively short period of time. [2]

People who study the specific effects of psychotropic substances classify DXM as a dissociative drug, a major subclass of hallucinogenic drugs, along with Ketamine and Phencyclidine. It generally does not produce withdrawal symptoms characteristic of physically addictive substances, but psychological addiction has been reported by some users.

DXM, when consumed in low recreational doses (usually under 200mg), is often described as having a buoyant, vaguely psychedelic effect similar to a mixture of alcohol, opiates, and marijuana. With higher doses, intense euphoria and vivid imagination may occur as bizarre feelings of dissociation increase. With very high doses, profound alterations in consciousness have been noted, and users often report out of body experiences or temporary psychosis. One of the unique features of a high dose DXM trip is the ability to relive past memories. Most users find such high doses to be extremely uncomfortable and most are unwilling to repeat it. Flanging (speeding up or slowing down) of sensory input also occurs, which is another unique feature of high dose DXM trips. In 1981, a paper by Gosselin estimated the lethal dose between 50 and 500 mg/kg.

Individual reactions to recreational doses of Dextromethorphan vary widely. Some find the effects of the drug to be immensely pleasurable, similar to a combination of opiates and hallucinogens, while others find that the drug produces dysphoria, panic, or dread.

Physical side effects that can occur after ingestion of recreational doses of DXM include a blotchy skin rash, itching (sometimes referred to as "robo itch," short for "Robitussin itch"), and sweating. Many people vomit from recreational doses or feel ill for the first part of the "trip". When taken in higher doses, physical side effects can include dilated pupils, difficulty urinating, increased urination frequency, extreme diarrhea, fever, tachycardia, loss of appetite, shakiness, seizures, and possible coma and death (however, in pure DXM, this has only been reported when doses exceed 2,000 mg).

Cannabinoids

Cannabinoids are a group of chemicals which activate the body's cannabinoid receptors. Before other types were discovered, the term referred to a unique group of secondary metabolites found in the cannabis plant, which are responsible for the plant's peculiar pharmacological effects. Currently, there are three general types of cannabinoids: herbal cannabinoids occur uniquely in the cannabis plant; endogenous cannabinoids are produced in the bodies of humans and other animals; and synthetic cannabinoids are similar compounds produced in a laboratory.

Cannabinoid receptors

Before the 1980s, it was often speculated that cannabinoids produced their physiological and behavioral effects via nonspecific interaction with cell membranes, instead of interacting with specific membrane-bound receptors. The discovery of the first cannabinoid receptors in the 1980s helped to resolve this debate. These receptors are common in animals, and have been found in mammals, birds, fish, and reptiles. There are currently two known types of cannabinoid receptors, termed CB1 and CB2.

CB1 receptors are found primarily in the brain, specifically in the basal ganglia and in the limbic system, including the hippocampus. They are also found in the cerebellum and in both male and female reproductive systems. CB1 receptors are essentially absent in the medulla oblongata, the part of the brain stem that is responsible for respiratory and cardiovascular functions. Thus, there is not a risk of respiratory or cardiovascular failure as there is with many other drugs. CB1 receptors appear to be responsible for the euphoric and anticonvulsive effects of cannabis.

CB2 receptors are almost exclusively found in the immune system, with the greatest density in the spleen. CB2 receptors appear to be responsible for the anti-inflammatory and possibly other therapeutic effects of cannabis.

- iso-Tetrahydrocannabinol-type *iso-THC*
- Cannabicyclol-type *CBL*
- Cannabicitran-type *CBT*

Natural cannabinoids, also called herbal cannabinoids and classical cannabinoids, are nearly insoluble in water but soluble in lipids, alcohols, and other non-polar organic solvents.

However, as phenols they form more water-soluble phenolate salts under strongly alkaline conditions. All natural cannabinoids are derived from their respective 2-carboxylic acids (2-COOH) by decarboxylation; that is, catalyzed by heat, light, or alkaline conditions. Natural cannabinoids are only known to occur naturally in the cannabis plant, and are concentrated in a viscous resin that is produced in glandular structures known as trichomes. In addition to cannabinoids, the resin is rich in terpenes, which are largely responsible for the odor of the cannabis plant.

There are over sixty known herbal cannabinoids. To the right the main classes of natural cannabinoids are shown. All classes derive from cannabigerol-type compounds and differ mainly in the way this precursor is cyclized.

Tetrahydrocannabinol (THC), cannabidiol (CBD) and cannabinol (CBN) are the most prevalent natural cannabinoids and have received the most study. Other common ones are listed below:

- CBG Cannabigerol

CBC Cannabichromene
CBL Cannabicyclol
CBV Cannabivarol
THCV Tetrahydrocannabivarin
CBDV Cannabidivarin
CBCV Cannabichromevarin
CBGV Cannabigerovarin
CBGM Cannabigerol Monoethyl Ether

THC is the primary psychoactive component of the plant. Medically, it appears to ease moderate pain and to be neuroprotective. THC has approximately equal affinity for the CB1 and CB2 receptors (Huffman 2000). Its effects are perceived to be more cerebral.

CBD is not psychoactive, and appears to moderate the euphoric effects of THC. It may decrease the rate of THC clearance from the body, perhaps by interfering with the metabolism of THC in the liver. Medically, it appears to relieve convulsion, inflammation, anxiety, and nausea. CBD has a greater affinity for the CB2 receptor than for the CB1 receptor. It is perceived to have more effect on the body.

CBN is the primary product of THC degradation, and there is usually little of it in a fresh plant. CBN content increases as THC degrades in storage, and with exposure to light and air. It is only mildly psychoactive, and is perceived to be sedative or stupefying.

These compounds may be in different forms depending on the position of the double bond in the alicyclic carbon ring. There is potential for confusion because there are different numbering systems used to describe the position of this double bond. Under the dibenzopyran numbering system widely used today, the major form of THC is called delta-9-THC, while the minor form is called delta-8-THC. Under the alternate terpene numbering system, these same compounds are called delta-1-THC and delta-6-THC, respectively.

Most herbal cannabinoid compounds are 21 carbon compounds. However, some do not follow this rule, primarily because of variation in the length of the side chain attached to the aromatic ring. In THC, CBD, and CBN, this side chain is a pentyl (5 carbon) chain. In the most common homologue, the pentyl chain is replaced with a propyl (3 carbon) chain. Cannabinoids with the propyl side chain are named using the suffix "varin", and are

designated, for example, THCV, CBDV, or CBNV. It appears that shorter chains increase the intensity and decrease the duration of the activity of the chemicals.

Cannabinoids were first discovered in the 1940s, when CBD and CBN were identified. The structure of THC was first determined in 1964. Due to molecular similarity and ease of synthetic conversion, it was originally believed that CBD was a natural precursor to THC. However, it is now known that CBD and THC are produced independently in the cannabis plant. Cannabinoid production starts when an enzyme causes geranyl pyrophosphate and olivetolic acid to combine and form CBG. Next, CBG is independently converted to either CBD or CBC by two separate synthase enzymes. CBC is then enzymatically cyclized to THC. For the propyl homologues (THCV, CBDV and CBNV), there is a similar pathway that is based on CBGV.

Cannabis plants can exhibit wide variation in the quantity and type of cannabinoids they produce. The mixture of cannabinoids produced by a plant is known as the plant's cannabinoid profile. Selective breeding has been used to control the genetics of plants and modify the cannabinoid profile. For example, strains which are used as fiber (commonly called hemp), are bred such that they are low in psychoactive chemicals like THC. Strains used in medicine are often bred for high CBD content, and strains used for recreational purposes are usually bred for high THC content, or for a specific chemical balance. Some strains of more than 20% THC have been created.

Quantitative analysis of a plant's cannabinoid profile is usually determined by gas chromatography (GC), or more reliably by gas chromatography combined with mass spectrometry (GC/MS). Liquid chromatography (LC) techniques are also possible, although these are often only semi-quantitative or qualitative. There have been systematic attempts to monitor the cannabinoid profile of cannabis over time, but their accuracy is impeded by the illegal status of the plant in many countries.

Cannabinoids can be administered by smoking, vaporizing, oral ingestion, transdermal patch, intravenous injection, sublingual absorption, or rectal suppository. Once in the body, most cannabinoids are metabolized in the liver, although some is stored in fat. Delta-9-THC is metabolized to 11-hydroxy-delta-9-THC, which is then metabolized to 9-carboxy-THC. Some cannabis metabolites can be detected in the body after several weeks.

Cannabinoids can be separated from the plant by extraction with organic solvents. Hydrocarbons and alcohols are often used as solvents. However, these solvents are flammable and many are toxic. Supercritical solvent extraction with carbon dioxide is an alternative technique. Although this process requires high pressures, there is minimal risk of fire or toxicity, solvent removal is simple and efficient, and extract quality can be well-controlled. Once extracted, cannabinoid blends can be separated into individual components using wiped film vacuum distillation or other distillation techniques. However, to produce high purity cannabinoids, chemical synthesis or semisynthesis is generally required.

Endogenous Cannabinoids

Endocannabinoids are naturally produced in the bodies of animals. After the first cannabinoid receptor was discovered in 1988, scientists began searching for natural compounds that activate these receptors.

In 1992, the first such compound was identified as arachidonoyl ethanolamide and named anandamide, a name derived from the Sanskrit word for bliss and amide. Anandamide is derived from the essential fatty acid arachidonic acid. It has a pharmacology similar to THC, although its chemical structure is different. Anandamide binds to both the central (CB1) and peripheral (CB2) cannabinoid receptors, and is found in nearly all tissues in a wide range of animals. It is about as potent as THC. Two analogs of anandamide, 7,10,13,16-docosatetraenoylethanolamide and homo-^{3}-linolenoylethanolamide, have similar pharmacology. All of these are members of a family of signalling lipids called N-acylethanolamides which also include the noncannabimimetic palmitoylethanolamide and oleoylethanolamide which have anti-inflammatory and orexigenic effects, respectively. Another endocannabinoid, 2-arachidonoyl glycerol, binds to both the CB1 and CB2 receptors, and is more abundant and less active than anandamide. Many N-acylethanolamides have also been identified in plant seeds and in molluscs. In 2001 was reported a third, ether-type endocannabinoid, 2-arachidonyl glyceryl ether (noladin ether), isolated from porcine brain. It binds to the CB1 cannabinoid receptor (Ki = 21.2 nM) and causes sedation, hypothermia, intestinal immobility, and mild antinociception in mice. It binds weakly to the CB2 receptor.

Endocannabinoids serve as intercellular 'messengers', signaling molecules that are released from one cell and activate the cannabinoid receptors present on other nearby cells. Although in this intercellular signaling role they are similar to the well-known monoamine neurotransmitters, such as acetylcholine, GABA or dopamine, endocannabinoids differ in numerous ways from them. Neurotransmitters are commonly small, water-soluble molecules that are contained within, and released from, tiny membrane-bound vesicles inside cells. Vesicles are often found in the tips, ‘terminals’, of long cellular branches called axons, and complex morphological and biochemical specializations mark the location from which vesicular release occurs. Endocannabinoids are lipophilic molecules that are not very soluble in water. They are not stored in vesicles, and exist as integral constituents of the membrane bilayers that make up cells. They are believed to be synthesized 'on-demand' rather than made and stored for later use. The mechanisms and enzymes underlying the biosynthesis of endocannabinoids remain elusive and continue to be an area of active research.

Conventional neurotransmitters are released from a ‘presynaptic’ cell and activate appropriate receptors on a ‘postsynaptic’ cell, where presynaptic and postsynaptic designate the sending and receiving sides of a synapse, respectively. Endocannabinoids are described as ‘retrograde’ transmitters because they most commonly travel ‘backwards’ against the usual synaptic transmitter flow. They are in effect released from the postsynaptic cell and act on the presynaptic cell, where the target receptors are densely concentrated on axonal terminals in the zones from which conventional neurotransmitters are released. Activation of cannabinoid receptors temporarily reduces the amount of conventional neurotransmitter released. This endocannabinoid mediated system permits the postsynaptic cell to control its

own incoming synaptic traffic. The ultimate effect on the endocannabinoid releasing cell depends on the nature of the conventional transmitter that is being controlled. When the release of the inhibitory transmitter, GABA, is reduced, the net effect is an increase in the excitability of the endocannabinoid-releasing cell. Conversely, when release of the excitatory neurotransmitter, glutamate, is reduced, the net effect is a decrease in the excitability of the endocannabinoid-releasing cell.

Endocannabinoids constitute a versatile system for affecting neuronal network properties in the nervous system.

Scientific American published an article in December of 2004, entitled "The Brain's Own Marijuana" discussing the endogenous cannabinoid system.

The current understanding recognizes the role that endocannabinoids play in almost every major life function in the human body. Cannabinoids act as a bioregulatory mechanism for most life processes, which reveals why medical cannabis has been cited as treatments for many diseases and ailments in anecdotal reports and scientific literature. Some of these ailments include: pain, arthritic conditions, migraine headaches, anxiety, epileptic seizures, insomnia, loss of appetite, GERD (chronic heartburn), nausea, glaucoma, AIDS wasting syndrome, depression, bipolar disorder (particularly depression-manic-normal), multiple sclerosis, menstrual cramps, Parkinson's, trigeminal neuralgia (tic douloureux), high blood pressure, irritable bowel syndrome, and bladder incontinence.

Synthetic & Patented Cannabinoids

Historically, laboratory synthesis of cannabinoids were often based on the structure of herbal cannabinoids and a large number of analogs have been produced and tested, especially in a group led by Roger Adams as early as 1941 and later in a group led by Raphael Mechoulam. Newer compounds are no longer related to natural cannabinoids or are based on the structure of the endogenous cannabinoids.

Synthetic cannabinoids are particularly useful in experiments to determine the relationship between the structure and activity of cannabinoid compounds, by making systematic, incremental modifications of cannabinoid molecules.

Other notable synthetic cannabinoids include:

- CP-55940 Produced in 1974, this synthetic cannabinoid receptor agonist is many times more potent than THC

HU-210 2-9 times as potent as THC

SR 141716A and SR 144528 CB1 and CB2 receptor antagonists, respectively

Nabilone Used as an anti-emetic in chemotherapy

Levonantradol Used as an anti-emetic and analgesic

Marinol Used as a presription medicine for appetite stimulation

Sativex A naturally based cannabis extract that contains both THC and CBD

Miscellaneous

- delta-9-Tetrahydrocannabinol (”**9**-THC, THC) and delta-8-tetrahydrocannabinol (”**8**-THC), mimic the action of anandamide, a neurotransmitter produced naturally in the body. The THCs produce the high

associated with marijuana by binding to the CB***1*** cannabinoid receptors in the brain.

- Tetrahydrocannabivarin (THCV), prevalent in certain South African and Southeast Asian strains of Cannabis. It is an antagonist of THC at CB***1*** receptors and attenuates the psychoactive effects of THC.
- Cannabidiol (CBD), non-psychoactive and not affecting psychoactivity of THC. CBD has anti-inflammatory effects. CBD is the precursor of THC and is the main cannabinoid in low-THC [Cannabis]() strains.
- Cannabinol (CBN), a degradation product of THC, produces a depressant effect
- Cannabichromene (CBC), non-psychoactive and not affecting psychoactivity of THC, a precursor of CBD and THC
- Cannabigerol (CBG), non-psychoactive

Tetrahydrocannabinol

Tetrahydrocannabinol (THC)

Chemical name

()-(6aR,10aR)-6,6,9-trimethyl-3-pentyl-6a,7,8,10a-tetrahydro-6H-benzo[c]chromen-1-ol

Chemical formula $C_{21}H_{30}O_{2}$

Molecular mass 314.46 g/mol

Glass transition 9.3 °C

Boiling point 155-157 °C (vacuum, 0.07 mbar)

Solubility (water) 2.8 mg/L (23 °C)

Solubility (saline) 0.77 mg/L (NaCl, 0.15 M)

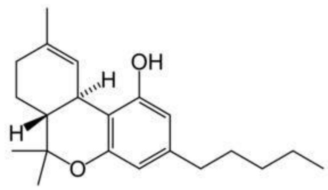
pKa 10.6

log P 3.78 (water @ pH 7 / octanol)

CAS number 1972-08-3

SMILES

CCCCCC(C=C1O)=CC2=C1[C@]3([H])[C@](C(C)(C)O2)([H])CCC(C)=C3



Tetrahydrocannabinol, also known as *THC*, *”***9***-THC*, *”***9***-tetrahydrocannabinol* (delta-9-tetrahydrocannabinol), *”^{1}-tetrahydrocannabinol* (using an older numbering scheme), or *dronabinol*, is the main psychoactive substance found in the Cannabis plant. It was isolated by Raphael Mechoulam and Yechiel Gaoni from the Weizmann Institute in Rehovot, Israel in 1964. In pure form it is a glassy solid when cold and becomes viscous and sticky if warmed. THC has a very low solubility in water, but a good solubility in most organic solvents such as ethanol or hexane. As in the case of nicotine and caffeine, THC's most likely function in Cannabis is to protect the plant from herbivores or pathogens [1].

Pharmacology

Its pharmacological actions are the result of its binding to the cannabinoid receptor CB1, located in the brain. The presence of these specialized receptors in the brain implied to researchers that endogenous cannabinoids were manufactured by the body, so the search began for a substance normally manufactured in the brain that binds to these receptors, the so-called natural ligand or agonist, leading to the eventual discovery of anandamide, 2 arachidonyl glyceride (2-AG) and other related compounds. This story resembles the discovery of the endogenous opiates (endorphins, enkephalins, and dynorphin), after the realization that morphine and other opiates bound to specific receptors in the brain.

THC has analgesic effects even at low doses that do not cause a "high", and cannabis was once commonly used to treat pain. Other effects include: relaxation; euphoria; altered space-time perception; alteration of visual, auditory, and olfactory senses; disorientation; fatigue; and appetite stimulation. It also has anti-emetic properties, and also may reduce aggression in certain subjects.

Toxicity

THC has a LD50 value of 1270 mg/kg (male rats) and 730 mg/kg (female rats) administered orally dissolved in sesame oil.

If this were scaled up to an adult human, the lethal dose would be between approximately 50 and 86 g for a 68 kg (150 lb) female or male person respectively. This would be equivalent to 1-1.8 kg of marijuana with a 5% THC content (roughly average) taken orally (much more if smoked). It is important to note, however, that toxicity studies in animal models do not necessarily correlate to human toxicity. THC receptor distribution in the rat CNS is different from that of humans, meaning that there is the significant possibility that toxicity in humans varies from the published animal LD***50*** studies. There has never been a documented fatality from marijuana or THC overdose.

Studies of the distribution of the cannabinoid receptors in the brain explain why THC's toxicity is so low (i.e., the LD50 of the compound is so large): parts of the brain that control vital functions such as respiration do not have many receptors, so they are relatively unaffected even by doses larger than could ever be ingested under any normal conditions.

Research

A number of studies indicate that THC may provide medical benefits for cancer and AIDS patients by increasing appetite and decreasing nausea, and by blocking the spread of some cancer-causing Herpes simplex viruses. It has been shown to assist some glaucoma patients by reducing pressure within the eye, and is used in the form of cannabis by a number of multiple sclerosis patients to relieve the spasms associated with their condition.

Studies also indicate a variety of negative effects associated with constant, long-term use, including short-term memory loss. However, other studies have refuted this, claiming the MRIs of long term users show little or no difference to MRIs of the non-using control group. The long-term effects of THC on humans have been disputed because its status as an illegal drug makes research difficult.

Preliminary research on synthetic THC has been conducted on patients with Tourette syndrome, with results suggesting that it may help in reducing nervous tics and urges by a significant degree. Animal studies suggested that Marinol and nicotine could be used as an effective adjunct to neuroleptic drugs in treating TS. Research on twelve patients showed that Marinol reduced tics with no significant adverse effects. A six-week controlled study on 24 patients showed the patients taking Marinol had a significant reduction in tic severity without serious adverse effects. Seven patients dropped out or had to be excluded from the study, one due to adverse side-effects. More significant reduction in tic severity was reported with longer treatment. No detrimental effects on cognitive functioning and a trend towards improvement in cognitive functioning were reported during and after treatment. Marinol's usefulness as a treatment for TS cannot be determined until/unless longer controlled studies on larger samples are undertaken.

Recent research has shown that many adverse side effects, generally known as the "stoner" stereotype, fail to hold up to the scientific method. Recent studies with synthetic cannabinoids show that activation of CB1 receptors can facilitate neurogeneration, as well as neuroprotection, and can even help prevent natural neural degredation from neurodegenerative diseases such as MS, Parkinson's, and Alzheimer's. This, along with research into the CB2 receptor (throughout the immune system), has given the case for medical marijuana more support.

THC, the main active component in marijuana, may protect the brain from the ravages of Alzheimer's disease, U.S. scientists reported. In lab experiments release on 10/09/2006, investigators from Scripps Research Institute in La Jolla, Calif., found THC appears to block an enzyme in the brain that causes plaques to form better than currently approved drugs.

Synthetic THC

Synthetic THC, also known under the substance name dronabinol, is available as a prescription drug (under the trade name Marinol) in several countries including the USA,

The Netherlands, and Germany. In the United States, Marinol is a Schedule III drug, available by prescription, considered to be non-narcotic and to have a low risk of physical or mental dependence. Efforts to get cannabis rescheduled as analogous to Marinol have not succeeded thus far. As a result of the rescheduling of Marinol from Schedule II to Schedule III, refills are now permitted for this substance. Marinol has been approved by the FDA in the treatment of anorexia in AIDS patients, as well as for refractory nausea and vomiting of patients undergoing chemotherapy.

An analog of dronabinol, nabilone, is available commercially in Canada under the trade name Cesamet, manufactured by Valeant. Cesamet has also received FDA approval for future availability in the United States and is a Schedule II drug.

In April 2005, Canadian authorities approved the marketing of Sativex, a mouth spray for multiple sclerosis to alleviate pain. Sativex contains tetrahydrocannabinol together with cannabidiol. It is marketed in Canada by GW Pharmaceuticals, being the first cannabis-based prescription drug in the world.

Chemical contraception - Hormonal contraception

Hormonal contraception refers to birth control methods that act on the hormonal system.

Currently, all hormonal contraceptives are designed for use by women rather than men, though research on a male hormonal contraceptive (“the male Pill”) has been underway for some time.

Hormonal contraceptives may be introduced into the woman’s body in many different ways, among them orally, vaginally, transdermally, or through injections or implants. The oral method was the first and most famous of these; within a few years of its introduction in 1960, "the Pill" became one of the most popular contraceptives in the United States and elsewhere, and it remains so today.

Hormonal contraception may act in one or more ways to prevent pregnancy. It may cause ovulation to cease, preventing the possibility of fertilization; it may thicken the woman’s cervical mucus, making penetration of the uterus by sperm more difficult; or it may alter and thin the endometrium so that a fertilized egg has difficulty implanting. (Technically, if the drug works in this third fashion, it acts as a contragestive rather than a contraceptive, since it has not prevented conception, acting instead to prevent gestation.)

Advantages

- If used properly, hormonal contraceptives are highly effective; except for abstinence, vasectomy, and tubal ligation, no other method of birth control has as great a degree of effectiveness.
- Hormonal contraceptives allow spontaneous intercourse.

Disadvantages

- Hormonal contraceptives offer no protection against sexually transmitted infections, placing non-monogamous individuals and couples at high risk for contracting such an infection.
- Like many other forms of birth control, hormonal contraceptives rely on the woman to use them correctly. Some, such as implants, require relatively little attention; others, such as injections or transdermal patches, require a schedule ranging from a week to several months. Still others—the wide varieties of oral contraception require a daily schedule. For example, many patient information leaflet for these pharmaceuticals suggest using a back up method of birth control if 2 or more doses are missed.[1]
- Hormonal contraceptives can have side effects, including: weight gain, loss of libido, hair loss, mood swings, bleeding between periods, nausea, breast tenderness, headaches, mastalgia, depression, ovarian cysts, constant bleeding (metrorrhagia), panic attacks, muscle pain, heart palpitations, pain during sex,

acne, abdominal cramps, dizziness, weakness or fatigue, leg cramps, nausea, vaginal discharge or irritation, bloating, swelling of the hands or feet, backache,insomnia, pelvic pain, rash, hot flashes,joint pain, convulsions, jaundice, urinary tract infections, and allergic reactions.

- Hormonal contraceptives can have serious health risks, such as ectopic pregnancy, decreased bone density, deep vein thrombosis, pulmonary embolus, uterine perforation, blood clot/stroke (stroke intensified risk for women who smoke) and death.
- Artificial contraception is objectionable to some religious traditions. These objections are furthered by the suggested, yet unproven post-fertilisation mode of action of preventing the implantation of a blastocyst.
- Hormonal contraceptives require a prescription in the United States and most other countries because of potential health risks.

Effects on rates of cancers

There is a mixed effect of combined hormonal contraceptives on the rates of various cancers, with the International Agency for Research on Cancer (IARC) concluding that "Combined oral contraceptives are carcinogenic to humans" and that "there is also conclusive evidence that these agents have a protective effect against cancers of the ovary and endometrium":[2]

- The (IARC) note that "the weight of the evidence suggests a small increase in the relative risk for breast cancer among current and recent users" which following discontinuation then lessens over a period of 10 years to similar rates as women who never used them.
- Small increases are also seen in the rates of cervical cancer and hepatocellular (liver) tumours.
- Endometrial and ovarian cancer risks are approximately halved and persists for at least 10 years after cessation of use; although "sequential oral contraceptives which were removed from the consumer market in the 1970s was associated with an increased risk for endometrial cancer".
- Studies have overall not shown effects on the relative risks for colorectal, malignant melanoma or thyroid cancers.
- Numerous studies have shown carcinogenicity in experimental animals.

Types of Hormonal Contraception

Oral Contraceptives

- Combined oral contraceptive pill -- known colloquially as "The Pill", it is a combined estrogen and progesterone pill which is taken daily at the same time.
- Progesterone only pill (POP)

Non-surgical devices

- Contraceptive patch - an adhesive patch containing hormones which is applied to the skin and worn continuously. It is changed each week for three weeks and removed for one week.
- Contraceptive vaginal ring ("NuvaRing") - a flexible ring containing estrogen and progesterone, it is inserted into the vagina and worn for three continuous weeks, removed for one week, then replaced with a new ring.

Surgical devices

- Implants - a set of small, flexible rods which contain progesterone, which are implanted under the skin. Norplant, an implant of this type, is being phased out of production, though Implanon, a newer implant, was approved in July of 2006, and Jadelle was approved in 1996.[3]
- Progesterone IntraUterine System - otherwise known as the IUS, this device is inserted into the uterus by a health care professional, where it continuously releases progesterone. It remains in the uterus for a period of years, as determined by the manufacturer.

Injections

- Lunelle - a monthly injection of progesterone, not currently available for sale.
- Depo Provera - an injection of progesterone administered every three months.

Most combined and progesterone-only pills may also be taken in high doses as emergency contraception (also known as the morning after pill). However, unlike plain copper IUDs, hormonal IUS is not approved for emergency contraception.

Cenchroman

Centchroman is sometimes mistaken for a hormonal contraceptive, probably because it is a pill that prevents pregnancy. Although it may be correctly termed a 'weekly contraceptive pill', it is not a hormonal contraceptive. Centchroman is a Selective Estrogen Receptor Modulator, or SERM. It causes ovulation to occur sooner than it normally would, while causing the lining of the uterus to build more slowly, which, together, prevent pregnancy. Centchroman is legally available only in India.

Depo Provera

B.C. type Hormonal

First use 1967

Failure rates *(per year)*

Perfect use 0.3%

Typical use 0.3%

Usage

Duration effect 90 days (12weeks + 5 days)

Reversibility ?-18+months

User reminders Maximum interval is just under 3 months

Clinic review 12 weeks

Advantages

Periods Usually no periods from 2nd injection

Benefits Especially if poor pill compliance. Reduced endometrial cancer risk.

Disadvantages

STD protection No

Periods Especially in 1st injection may be frequent spotting

Weight gain Yes

Risks Reduced bone density; possible risk of breast cancer, cervical cancer.

Medical notes

For those intending to start family, suggest switch 6 months prior to alternative method (eg POP) allowing more reliable return fertility.

Depo-Provera is a contraceptive or birth control product which is injected every 3 months.

It is the brand name for medroxyprogesterone acetate manufactured by Pfizer Inc. It is a hormonal birth control method containing the pregnane (17±-hydroxyprogesterone derivative) progestin medroxyprogesterone acetate, without estrogen, and is administered to women in the form of an intramuscular injection once every 11 to 13 weeks. Depo-Provera causes the ovaries to stop releasing eggs.

How it works

The mechanism of action of progestin-only contraceptives depends on the progestin activity and dose.[1][2] High dose progestin-only contraceptives, such as the injectable Depo-Provera, completely inhibit follicular development and ovulation. Like all progestin-only contraceptives, Depo-Provera also has a progestogenic effect of increasing cervical mucus viscosity, thereby inhibiting sperm penetration. In anovulatory cycles using progestin-only contraceptives, the endometrium is thin and atrophic. If the endometrium was also thin and atrophic during an ovulatory cycle, this could theoretically interfere with implantation of a blastocyst (embryo).

Benefits

- Near 100% effective at preventing pregnancy.
- Injected every 3 months. The only continuing action is to book subsequent follow-up injections every twelve weeks, and to monitor side effects to insure that they do not require medical attention.
- 80% reversible within 12 months and 95% reversible within 18 months
- Depo-Provera reduces the risk of endometrial cancer by 80%.[3][4][5] The reduced risk of endometrial cancer in Depo-Provera users is thought to be due to both the direct anti-proliferative effect of progestogen on the endometrium and the indirect reduction of estrogen levels by suppression of ovarian follicular development.[6]

Pregnancy and breastfeeding

Depo Provera may be used by breast-feeding mothers. Heavy bleeding is possible if given in the immediate postpartum time and is best delayed until six weeks after birth. It may be used within five days if not breast feeding. While a small study "showed no significant difference in birth weights or incidence of birth defects" and "no significant alternation of immunity to infectious disease caused by breast milk containing DMPA", a possible subgroup of babies with 75% higher incidence of infectious disease was seen in mothers who started Depo Provera at 2 days postpartum.[7] A larger study with longer follow-up concluded that "use of DMPA during pregnancy or breastfeeding does not adversely affect the long-term growth and development of children". This study also noted that "children with DMPA

exposure during pregnancy and lactation had an increased risk of suboptimal growth in height," but that "after adjustment for socioeconomic factors by multiple logistic regression, there was no increased risk of impaired growth among the DMPA-exposed children." "Unfavorable socioeconomic factors" may therefore result in suboptimal height for DMPA-exposed children. The study also noted that effects of DMPA exposure on puberty require further study, as so few children over the age of 10 were observed.[8]

Disadvantages and side effects

Warnings and precautions

- Takes two weeks to take effect
- Offers no protection against Sexually transmitted diseases(STDs)
- Depo Provera can affect menstrual bleeding. After a year of use, 55% of women experience amenorrhoea; after 2 years, the rate rises to 68%. In the first months of use "irregular or unpredictable bleeding or spotting, or rarely, heavy or continuous bleeding" was reported.[9] Some women may prefer amenorrhea. According to Jerilynn Prior, M.D., professor of endocrinology and metabolism at the University of British Columbia in Vancouver, and board member for the Society for Menstrual Cycle Research,"the most important thing to emphasize about menstrual suppression is that the long-term effects are simply unknown," and "allowing the one vital sign unique to women to go unmonitored...could ultimately lead to an enormous uncontrolled experiment with a woman's health." [10]
- Return to fertility may be slow. Fifty percent of women may be able to conceive in about 10 months from the last injection, but fertility may be totally suppressed in some women for up to 18 months or more.[9]
- Long-term studies of users of Depo-Provera have found slight or no increased overall risk of breast cancer. However, one subset of the study population did show an increased risk of breast cancer in recent users (Depo use in the last four years) under age 35.[9]
- Infants born to women exposed to Depo during pregnancy in one study had an 80% greater chance of dying in the first year of life.[11]

Black box warning

While it has long been known that Depo-Provera causes bone loss, it has recently been discovered that the osteoporotic effects of the injection grow worse the longer Depo-Provera is administered, last long after the injections are stopped, and may be irreversible. For this reason, on November 17, 2004 the United States Food and Drug Administration and Pfizer agreed to put a "black box warning" on Depo-Provera's label.[12] However, the WHO (World Health Organization)—which provided Depo-Provera to developing countries when the US

FDA refused to approve it for safety reasons pertaining to breast cancer—advises that the use of Depo Provera should not be restricted. [13][14]

It is unclear whether the bone density loss associated with Depo-Provera use is reversible, and if so, how completely. Three studies have suggested that bone loss is reversible after the discontinuation of Depo-Provera, although one notes that bone loss was not reversible in long-term users of Depo-Provera, and the others were conducted in part by a Pfizer consultant. [15][16][17] Other studies have suggested that the effect of Depo-Provera use on post-menopausal bone density is minimal,[18] perhaps because Depo users experience less bone loss at menopause.[19] However, as of 2006, no study has directly examined fracture risk in post-menopausal women who have used Depo-Provera; therefore, the risk is unknown. Pfizer and the FDA recommend that Depo-Provera not be used for longer than 2 years, unless there is no viable alternative method of contraception, due to concerns over bone loss.[12]

Side effects

Depo-Provera may have side effects including irregular menstrual bleeding, no mentrual bleeding, constant bleeding (metrorrhagia), severe headaches, weight gain, weight loss, panic attacks, muscle pain, heart palpitations, pain during sex, acne, abdominal cramps, dizziness, weakness or fatigue, leg cramps, nausea, vaginal discharge or irritation, breast swelling and tenderness, bloating, swelling of the hands or feet, backache, depression,insomnia, pelvic pain, no hair growth or excessive hair loss, rash, hot flashes,joint pain, convulsions, jaundice, urinary tract infections, allergic reactions, fainting, paralysis, deep vein thrombosis, and pulmonary embolus.[9]

Related studies

- A study of 819 women in one city found an association between using Depo-Provera and higher incidence of chlamydia and gonorrhea.[20]
- A study of 28 rhesus monkeys linked progesterone implants (similar to, but not identical to Depo Provera) to an eightfold increase in SIV contraction.[21] While studies have not been performed on humans or with HIV, this may suggest an enhanced risk of HIV transmission.[22]
- A study in mice found that Depo Provera may simultaneously increase susceptibility to the herpesvirus and decrease immune response to the herpesvirus. [23]
- Depo Provera, exacerbates glutamate excitotoxicity, which may render users more vulnerable to neurodegeneration. [24]

Contraindications

Women with the following conditions should not use Depo Provera:

- stroke
- currently pregnant

- current or past breast cancer
- liver problems or liver disease
- blood clots

Other uses

Depo-Provera is also used with male sex offenders as a form of chemical castration as it has the effect of drastically reducing sex drive in males.

Controversy over Approval of Depo

There is a long, controversial history regarding the approval of Depo Provera by the FDA. The original manufacturer, Upjohn, applied repeatedly for approval--which was repeatedly denied. Points in the controversy include:

- Animal testing for carcinogenicity. Depo Provera caused breast cancer tumors in dogs. Critics of the study claimed that dogs are more sensitive to artificial progesterone, and that the doses were too high to extrapolate to humans. The FDA pointed out that all substances carcinogenic to humans are carcinogenic to animals as well, and that if a substance is not carcinogenic it does not register as a carcinogen at high doses. Levels of Depo Provera which caused malignant mammary tumors in dogs were equivalent to 25 times the amount of the normal luteal phase progesterone level for dogs. (Which is lower than the pregnancy level of progesterone for dogs, and is species-specific.)[3] Depo Provera caused endometrial cancer in monkeys--2 of 12 monkeys tested, the first ever recorded cases of endometrial cancer in rhesus monkeys.[25] Speaking in comparative terms regarding animal studies of carcinogenicity for drugs, a member of the FDA's Bureau of Drugs testified at an agency Depo hearing, "...Animal data for this drug is more worrisome than any other drug we know of that is to be given to well people."
- Bias of OB-GYN committee. The OB-GYN Committee, which advised the FDA to approve Depo on the two occaisons when it was not approved, was not capable of objectivity according to senior FDA officials/a former director of the FDA bureau of drugs, because members of the committee were in "the population control business."[25]
- Cervical cancer in Upjohn/NCI studies. Cervical cancer was found to be increased as high as 9-fold in the first human studies recorded by the manufacturer and the National Cancer Institute. [26]
- Coercion and Lack of Informed Consent. Testing/use of Depo was focused almost exclusively on women of color in developing countries, (especially Thailand, during the years that it was a US sponsored military dictatorship) and poor women of color in the US, raising serious questions about coercion and lack of informed consent, particularly for the illiterate[27] and for the mentally retarded, who were given Depo long-term merely to eliminate "menstrual hygiene."[28]

- Atlanta/Grady Study. Upjohn studied the effect of Depo for 11 years in Atlanta--mostly on black women who were receiving public assistance-- but did not file any of the required follow-up reports with the FDA. Investigators who eventually visited noted that the studies were disorganized. They found that data collection was questionable, consent forms and protocol were absent; that those women whose consent had been obtained at all were not told of possible side effects. Women whose known medical conditions indicated that use of Depo would endanger their health were given the shot. Several of the women in the study died; some of cancer, but some for other reasons, such as suicide due to depression. Over half the 13,000 women in the study were lost to followup due to sloppy record keeping. Consequently, no data from this study was usable.
- WHO Review. In 1992, the WHO presented a review of Depo in four developing countries to the FDA. The National Women's Health Network and other women's organizations testified at the hearing that the WHO was not objective--that the WHO could not advise the FDA not to approve Depo after they had already distributed it in developing countries. The WHO's objectivity has recently also been criticized for receiving donations from pharmaceutical companies.[29]. Depo was approved for use in US on the basis of the WHO review of previously submitted evidence from countries such as Thailand, evidence which the FDA had deemed insufficient and too poorly designed for assessment of cancer risk at a prior hearing. The Alan Guttmacher Institute has speculated that US approval of Depo may increase its availability and acceptability in developing countries. [30]
- FDA scientists report concern about their ability to voice scientific concern or inform the public about unsafe drugs, something they did not report in the years approval for Depo was rejected.[31]

Aftermath

- In 1995, women's health groups asked the FDA to put a moratorium on Depo Provera, and to institute informed consent forms following a universal standard.[32]
- Scientists and women's groups in India continue to oppose Depo Provera.[33]In 2002, Depo was removed from the family planning protocol in India.
- One in five black teenagers using birth control in the US uses Depo Provera--a far higher rate of use than for white teenagers. Activists claim this is because black teenagers are disproportionately targeted for the least safe contraceptives.[34]
- The Canadian Coalition on Depo-Provera, a coalition of women's health professional and advocacy groups, opposed the approval of Depo in Canada.[35] Since the approval of Depo in Canada in 1997, a $700 million dollar class action lawsuit has been filed against Pfizer.[36]

Oral contraceptive

Combined Oral Contraceptive Pill (COCP)

Background
B.C. type Hormonal

First use 1960

Failure rates (per year)

Perfect use 0.1%

Typical use 2.15 - 8.0%

Usage

Duration effect 1-4days

Reversibility Yes

User reminders Taken within same 12hour window each day

Clinic review 6 months

Advantages

Periods Regulates, and often lighter and less painful

Benefits Reduced ovarian and endometrial cancer risk. May treat acne, PCOS, endometriosis

Disadvantages

STD protection No

Weight gain Possible

Risks Incr. DVTs, strokes, breast cancer

Medical notes

Affected by broad-spectrum antibiotics, the herb Hypericum (St.Johns Wort) and some anti-epileptics, also vomiting or diarrhoea. Caution if history migraines.

Oral contraceptives, often referred to as "the Pill", are chemicals taken by mouth to inhibit normal fertility. All act on the hormonal system. Oral contraceptives have been on the market since 1960, and enjoy great popularity. They are used by millions of women around the

world, but usage prevalence varies: one quarter of reproductive age women in the United Kingdom take the pill,[1] but only 1% of women in Japan.[2] Male oral contraceptives remain a subject of research and development.

History

By the 1930s, scientists had isolated and determined the structure of the steroid hormones and found that high doses of androgens, estrogens or Progesterone inhibited ovulation, but obtaining them from European pharmaceutical companies produced from animal extracts was extraordinarily expensive.

In 1939, Russell Marker, a professor of organic chemistry at Pennsylvania State University, developed a method of synthesizing progesterone from plant steroid sapogenins, initially using sarsapogenin from sarsaparilla which proved too expensive. After three years of extensive botanical research he discovered a much better starting material, diosgenin from inedible Mexican wild yams found in the jungles of Veracruz near Orizaba. Unable to interest his research sponsor Parke-Davis in the commercial potential of synthesizing progesterone from Mexican yams, Marker left Penn State and in 1944 co-founded Syntex with two partners in Mexico City before leaving Syntex a year later. Syntex broke the monopoly of European pharmaceutical companies on steroid hormones, reducing the price of progesterone almost 200-fold over the next eight years.[3]

Midway through 20th century, the stage was set for the development of a hormonal contraceptive, but pharmaceutical companies, universities and governments showed no interest in pursuing research.

In early 1951, reproductive physiologist Gregory Pincus, a leader in hormone research and co-founder of the Worcester Foundation for Experimental Biology (WFEB) in Shrewsbury, Massachusetts, first met American birth control movement founder Margaret Sanger at a Manhattan dinner hosted by Abraham Stone, medical director and vice president of Planned Parenthood (PPFA), who helped Pincus obtain a small grant from PPFA to begin hormonal contraceptive research. Research started on April 25, 1951 with reproductive physiologist Min Chueh Chang repeating and extending the 1937 experiments of Makepeace et al. that showed injections of progesterone suppressed ovulation in rabbits. In October 1951, G. D. Searle & Company refused Pincus' request to fund his hormonal contraceptive research, but retained him as a consultant and continued to provide chemical compounds to evaluate.

In March 1952, Sanger wrote a brief note mentioning Pincus' research to her longtime friend and supporter, suffragist and philanthropist Katharine Dexter McCormick, who visited the WFEB and its co-founder and old friend Hudson Hoagland in June 1952 to learn about contraceptive research there. Frustrated when research stalled from PPFA's lack of interest and meager funding, McCormick arranged a meeting at the WFEB on June 6, 1953 with Sanger and Hoagland where she first met Pincus who committed to dramatically expand and accelerate research with McCormick providing fifty times PPFA's previous funding.

Pincus and McCormick enlisted Harvard clinical professor of gynecology John Rock, an expert in the treatment of infertility, to lead clinical research with women. At a scientific conference in 1952, Pincus and Rock, who had known each other for many years, discovered they were using similar approaches to achieve opposite goals. In 1952, Rock induced a three-

month anovulatory "pseudo-pregnancy" state in eighty of his infertility patients with continuous gradually increasing oral doses of estrogen (diethylstilbestrol 5–30 mg/day) and progesterone (50–300 mg/day) and within the following four months an encouraging 15% became pregnant.

In 1953, at Pincus' suggestion, Rock induced a three-month anovulatory "pseudo-pregnancy" state in twenty-seven of his infertility patients with an oral 300 mg/day progesterone-only regimen for 20 days from cycle days 5–24 followed by pill-free days to produce withdrawal bleeding. This produced the same encouraging 15% pregnancy rate during the following four months without the troubling amenorrhea of the previous continuous estrogen and progesterone regimen. But 20% of the women experienced breakthrough bleeding and in the first cycle ovulation was suppressed in only 85% of the women, indicating that even higher and more expensive oral doses of progesterone would be needed to initially consistently suppress ovulation.

Pincus asked his contacts at pharmaceutical companies to send him chemical compounds with progestogenic activity. Chang screened over 200 chemical compounds in animals and found the three most promising were Syntex's norethindrone and Searle's norethynodrel and norethandrolone.

Chemists Carl Djerassi, Luis E. Miramontes and George Rosenkranz at Syntex in Mexico City had synthesized the first orally highly active progestin norethindrone in 1951.[4] Chemist Frank B. Colton at Searle in Skokie, Illinois had synthesized the orally highly active progestins norethynodrel (an isomer of norethindrone) in 1952 and norethandrolone in 1953.

In December 1954, Rock began the first tests of the ovulation-suppressing potential of 5–50 mg doses of the three oral progestins for three months (for 21 days per cycle—days 5–25 followed by pill-free days to produce withdrawal bleeding) in fifty of his infertility patients in Brookline, Massachusetts. 5 mg doses of norethindrone or norethynodrel and all doses of norethandrolone suppressed ovulation but caused breakthrough bleeding, but 10 mg and higher doses of norethindrone or norethynodrel suppressed ovulation without breakthrough bleeding and led to a 14% pregnancy rate in the following five months. Pincus and Rock selected Searle's norethynodrel for the first contraceptive trials in women citing its total lack of androgenicity versus Syntex's norethindrone's very slight androgenicity in animal tests.

Norethynodrel (and norethindrone) were subsequently discovered to be contaminated with a small percentage of the estrogen mestranol (an intermediate in their synthesis), with the norethynodrel in Rock's 1954-5 study containing 4-7% mestranol. When further purifying norethynodrel to contain less than 1% mestranol led to breakthrough bleeding, it was decided to intentionally incorporate 2.2% mestranol, a percentage that was not associated with breakthrough bleeding, in the first contraceptive trials in women in 1956. The norethynodrel and mestranol combination was given the proprietary name Enovid.

The first contraceptive trial of Enovid led by Edris Rice-Wray Carson began in April 1956 in Río Piedras, Puerto Rico. A second contraceptive trial of Enovid (and norethindrone) led by Edward T. Tyler began in June 1956 in Los Angeles. On January 23, 1957, Searle held a symposium reviewing gynecologic and contraceptive research on Enovid through 1956 and concluded Enovid's estrogen content could be reduced by 50% to lower the incidence of

estrogenic gastrointestinal side effects without significantly increasing the incidence of breakthrough bleeding.

In June 1957, the FDA approved Enovid 10 mg (9.85 mg norethynodrel and 150 µg mestranol) for menstrual disorders based on data from its use by more than 600 women. Numerous additional contraceptive trials showed Enovid at 10, 5, and 2.5 mg doses to be highly effective. On July 23, 1959, Searle filed a supplemental application to add contraception as an approved indication for 10, 5 and 2.5 mg doses of Enovid. The FDA refused to consider the application until Searle agreed to withdraw the lower dosage forms from the application. On May 9, 1960, the FDA announced it would approve Enovid 10 mg for contraceptive use, which it did on June 23, 1960, by which time Enovid 10 mg had been in general use for three years during which time, by conservative estimate, at least half a million women had used it.

Although FDA approved for contraceptive use, Searle never marketed Enovid 10 mg as a contraceptive. Nine months later, in February 1961, the FDA approved Enovid 5 mg for contraceptive use. In July 1961, Searle finally began marketing Enovid 5 mg (5 mg norethynodrel and 75 µg mestranol) to physicians as a contraceptive.

Although the FDA approved the first oral contraceptive in 1960, contraceptives were not available to married women in all states until Griswold v. Connecticut in 1965 and were not available to unmarried women in all states until Eisenstadt v. Baird in 1972.

The first published case report of a blood clot and pulmonary embolism in a woman using Enovid did not appear until November 1961, four years after its approval, by which time it had been used by over one million women. It would take almost a decade of epidemiological studies to conclusively establish an increased risk of venous thrombosis in oral contraceptive users and an increased risk of stroke and myocardial infarction in oral contraceptive users who smoke or have high blood pressure or other cardiovascular or cerebrovascular risk factors. These risks of oral contraceptives were dramatized in the 1969 book A Doctor's Case Against the Pill by feminist journalist Barbara Seaman who helped arrange the 1970 Senate hearings called by Senator Gaylord Nelson. The hearings were conducted by Senators who were all men and the witnesses in the first round of hearings were all men, leading Alice Wolfson and other feminists to protest the hearings and generate media attention. Their work led to mandating the inclusion of patient package inserts with oral contraceptives to explain their possible side effects and risks to help facilitate informed consent.[5] Today's standard dose oral contraceptives contain an estrogen dose that is one third lower than the first marketed oral contraceptive and contain lower doses of different, more potent progestins in a variety of formulations.

France

In 1967, the Neuwirth Law legalized contraception in France, including the pill. [6] The pill is the most popular form of contraception in France, especially among young women. The abortion rate has remained stable since the introduction of the pill. [7]

Japan

In Japan, lobbying from the Japan Medical Association prevented the Pill from being approved for nearly 40 years. Two main objections raised by the association were safety concerns over long-term use of the Pill, and concerns that the Pill use would lead to diminished use of condoms and thereby potentially increase sexually transmitted infection (STIs) rates.[8] Some voiced suspicions that potential loss of income due to lower abortion rates that could result from Pill use might have been a factor in the organization's objection. The association responded to its critics by pointing out that doctors would have received higher monetary compensation from prescribing pills, given Japan's national health insurance system. As of 2004, condoms accounted for 80% of birth control use in Japan, and this may explain Japan's comparably low rates of AIDS.[9]

The Pill was finally approved for use in 1999; however, the Pill prescription guidelines the government endorsed are quite stringent. They require Pill users to visit a doctor every three months for pelvic examinations and undergo tests for sexually transmitted diseases and uterine cancer. In the United States and Europe, in contrast, an annual or bi-annual clinic visit is standard for Pill users. As a possible result of the stringent regulations, very few women in Japan use the Pill.[2] For a detailed discussion of abortion and pill politics in Japan see Tiana Norgren (2001) Abortion before Birth Control.

Seasonale

Starting in 2003, women have also been able to use a three-month version of the Pill.[10] Similar to the effect of using a constant-dosage formulation and skipping the placebo weeks for three months, Seasonale gives the benefit of less frequent periods, at the potential drawback of breakthrough bleeding. Seasonique is another version in which the placebo week every three months is replaced with a week of low-dose estrogen.

Use

Oral contraceptives for women consist of a pill taken daily which contains doses of synthetic hormones (always a progestin and most often also an estrogen).

Combined oral contraceptive pills (which contain both a progestin and an estrogen) must be ingested within 12 hours of the same time each day and progesterone only pills (POPs) within 3 hours. Most brands of combined pills are packaged with 21 days of active (hormone-containing) pills followed by either 7 days of placebo pills, or instructions to not take pills for seven days. A woman on the pill will have a withdrawal bleed, or period, sometime during the placebo week. POPs are taken continuously; most women experience somewhat irregular bleeding while taking them.

If a woman just starting the pill begins taking them on the first day of her menstrual cycle (first day of red bleeding), she will have pregnancy protection from the very first pill. If a woman begins taking the pill at another time in her menstrual cycle, she must use a different form of contraception for seven days.

Mechanism of action

Several different types of 'the Pill' exist. Generally, all oral contraceptives have different synthetic estrogens and progestins, chemical analogues of the natural hormones, estradiol (an estrogen) and Progesterone (a Progestagen). An exception is the progestin only pill, which lacks estrogen and thus generally has fewer side effects than the combined pill.

The combined Pill primarily prevents pregnancy by preventing ovulation. It also has the side effect of thickening the cervical mucus, which can prevent or slow sperm entry into the uterus. In addition, the Pill thins the endometrium (the lining of the uterus).

Contraception vs Abortion debate

There are physicians and other medical professionals who point to this thinning of the endometrium as evidence that the Pill is an abortifacient.[11] This claim is based on experiences with in vitro fertilization which demonstrated that thinner uterine linings correlated with increased difficulty in getting the test-tube-fertilized blastocyst to implant. However, other physicians (including some pro-life physicians) are unconvinced that this truly does decrease the likelihood that an embryo will implant itself in the uterine lining.

In women who do not take The Pill, the uterine lining is usually unreceptive to implantation prior to ovulation. The purpose of the hormones released by the corpus luteum is to cause the endometrium to thicken and become receptive to implantation (which occurs between six and twelve days after ovulation if the ovum is fertilized). Thus, simple observations that the uterine lining is too thin to support implantation during a cycle where no ovulation has occurred is insufficient to support the claim that there is a reduced likelihood of implantation in ovulatory Pill cycles. Currently, no research has been conducted on the behavior of the endometrium in ovulatory Pill cycles.[12]

The theory that the pill has postfertilization effects is also based on some studies that found the ratio of extrauterine to intrauterine ratio of pregnancies increases by 70–1390% in women using the pill[13][14][15] although not all research reaches the same conclusions.[16] The asserted increased proportion of extrauterine pregnancies is most likely explained by interference of the pill with the normal process of implantation.

There is some controversy over the beginning of pregnancy. The medical consensus is that pregnancy begins with implantation, not fertilization. However some medical sources still define pregnancy as beginning with fertilization. Therefore, if oral contraceptives do interfere with implantation, the determination of whether oral contraceptives are abortifacients depends largely on a person's individual definition of pregnancy.

Effectiveness

The Pearl Index is often used to compare the effectiveness of various methods of contraception.[17] It is expressed as the "number of unintended pregnancies in 100 normally fertile women over the period of one year". Each method of birth control has two Pearl index numbers:

- method effectiveness: is the Pearl index number for use under perfect conditions. The method effectiveness Pearl index for the Pill has been measured as low as 0.3 and as high as 1.25, which means that under ideal conditions, anywhere from 0.3 to 1.25 out of 100 users will become pregnant during one year of perfect use (Pearl index = 0.3 to 1.25).
- user effectiveness or typical effectiveness: is the Pearl index number for use that is not consistent or always correct. The user effectiveness measured by the Pearl index for the Pill has been measured as low as 2.15 and as high as 8.0, which means that anywhere from 2.15 to 8.0 out of 100 women will become pregnant during the first year of typical use (Pearl index = 2.15 to 8.0).[18][19]

Many women occasionally forget to take the Pill daily, impairing its effectiveness. Correct use of the pill usually implies taking it every day at the same hour for 21 days, followed by a pause of seven days.

Use of other medications can prevent the Pill from working, due to interactions with the metabolism of the hormonal constituents. Diarrhea can also stop the Pill from working, because it causes the hormones to not be properly absorbed by the bowels.

Packaging

The Pill usually comes in two different packet sizes, with days marked off for a 28 day cycle. For the 21-pill packet, a pill is consumed daily for three weeks, followed by a week of no pills. For the 28-pill packet, 21 pills are taken, followed by week of placebo or sugar pills.

The purpose of the placebo pills is that the user, out of habit, can take a pill on every day of her menstrual cycle, instead of calculating the date she should start the next dose. Failure to take placebos has no effect on the effectiveness of the pill provided the regular schedule is followed. If the pill formulation is monophasic, it is possible to skip menstruation and still remain protected against conception by skipping the placebo pills and starting directly with the next packet. Attempting this with bi- or tri-phasic pill formulations carries an increased risk of breakthrough bleeding and may be undesirable. It will not, however, increase the risk of getting pregnant. The presence of placebo pills is thought to be comforting, as menstruation is a physical confirmation of not being pregnant. Breakthrough bleeding also becomes a more common side effect as a woman attempts to go longer periods of time between menstrual periods. The pills may contain an iron supplement, as iron requirements increase during menstruation.

Drug interactions

Some drugs reduce the effect of the Pill and can cause breakthrough bleeding, or increased chance of pregnancy. These include enzyme inducing drugs such as rifampicin antibiotic, barbiturates, phenytoin and carbamazepine. In addition cautions are given about broad spectrum antibiotics, such as ampicillin and doxycycline, which may cause problems "by impairing the bacterial flora responsible for recycling ethinyloestradiol from the large bowel" (BNF 2003).[20]

The traditional medicinal herb St John's Wort has also been implicated due to its upregulation of the P450 system in the liver.

Side-effects

When starting to take the Pill, the majority (about 60%) of women report no side effects at all, and the vast majority of those who do, have only minor effects.[21][22][23] Some women report slight weight gain, although most studies show that the incidences of this is about 50% and as many women experience slight weight loss. Some women also notice changes in the intensity of sexual desire, vaginal discharge and menstrual flow.

Other possible side effects are: breakthrough bleeding, unusual build-up of the uterine lining, nausea, headaches, depression, vaginitis, urinary tract infection, changes in the breasts, changes in blood pressure, skin problems, skin improvements, and gum inflammation. The insert included with each pill packet usually has a more extensive list of recognized side effects.

There is contradictory research into the risk of breast cancer.[24] There "is a small increase in the risk of having breast cancer diagnosed in current users of combined oral contraceptives and in women who had stopped use in past 10 years but there is no evidence of an increase in the risk more than 10 years after stopping use" and the nature of the identified cancers being less advanced clinically suggested a bias of screening in oral contraceptives users.[25]

Effects on sexuality

Some say the Pill may have a positive effect on a woman's sexuality. Because neither the woman (who uses the Pill) nor her partner need take any special action before or during intercourse, it makes birth control "invisible" and sex spontaneous, more natural, or both. When combined with the Pill's high degree of effectiveness, this may enable the couple, and especially the woman, to relax more easily during sex. Masters and Johnson reported more than one woman who experienced her first orgasm during intercourse shortly after going on the Pill.

However, some also say the Pill can also have a negative effect on a woman's sexuality. One doctor (Dr. John Bancroft, a senior research fellow at the Kinsey Institute at Indiana University) estimates that one in four women on the pill experience some negative sexual effect. These effects may include a decreased frequency of sexual thoughts, increased difficulty in becoming aroused, or decreased lubrication, which can make sex painful. Recent research co-authored by Dr. Irwin Goldstein (a urologist in Boston) suggests such effects may continue for up to four months after a woman stops taking the Pill.[26]

Cautions and contraindications

Oral contraceptives may influence coagulation, subtly increasing the risk of deep venous thrombosis (DVT) and pulmonary embolism, stroke and myocardial infarction (heart attack). However, estrogen contraceptives are usually only contraindicated in women with pre-existing cardiovascular disease, in women who have a familial tendency to form blood clots (such as familial factor V Leiden), women with severe obesity and/or hypercholesterolaemia (high cholesterol level) and most notably in smokers over 35.

Studies of higher-dose, estrogen-based pills have been linked to an increased risk of breast cancer, though no studies have been done on the lower-dose pills more popular today. In rare cases, high estrogen Pills may trigger benign intracranial hypertension.

In Our Sexuality, Crooks and Baur state a commonly held medical opinion about risks associated with Pill use: "In general, the health risks of oral contraceptives are far lower than those from pregnancy and birth."[27] Although widely accepted,[28] at least one organization disputes that conclusion,[29] and others have argued that comparing a contraceptive method to no method (pregnancy) is not relevant - instead, the comparison of safety should be among available methods of contraception.[30]

Non-Contraceptive Uses

The hormones in "the Pill" can be used to treat some medical conditions, such as polycystic ovary syndrome (PCOS), endometriosis, adenomyosis, anemia related to menstruation, and painful menstruation (dysmenorrhea). In addition, oral contraceptives are often prescribed as medication for mild or moderate acne.[31] The pill can also induce bleeding on a regular schedule for women bothered by irregular menstrual cycles and certain disorders where there is dysfunctional uterine bleeding.

Combined oral contraceptive use reduces the risk of ovarian cancer by 40% and the risk of endometrial cancer by 50% compared to never users. The risk reduction increases with duration of use, with an 80% reduction in risk for both ovarian and endometrial cancer with use for more than 10 years. The risk reduction for both ovarian and endometrial cancer persists for at least 20 years.[32]

Although the FDA does not officially condone the use of the Pill as a minor breast enhancer, many women have gone on the pill in order to increase their breast size. This results from the low doses of estrogen present along with the progestin. Results vary widely.

Social and cultural impact

Introduced at the beginning of the tumultuous decade of the 1960s, the Pill had a big social impact. In the first place, it was far more effective than any previous method of birth control, giving women unprecedented control over their fertility. Its use was separate from intercourse, requiring no special preparations at the time of sexual activity that might interfere with spontaneity or sensation. This combination of factors served to make the Pill immensely popular within a few years of its introduction.[33][34]

Because the Pill was so effective, and soon so widespread, it also heightened the debate about the moral and health consequences of pre-marital sex and promiscuity. Never before had sexual activity been so divorced from reproduction. For a couple using the Pill, intercourse became purely an expression of love, or a means of physical pleasure, or both; but it was no longer a means of reproduction. While this was true of previous contraceptives, their relatively high failure rates and their less widespread use failed to emphasize this distinction as clearly as did the Pill. The spread of oral contraceptive use thus led many religious figures and institutions to debate the proper role of sexuality and its relationship to procreation. The Catholic Church in particular, after studying the phenomenon of oral contraceptives, re-emphasized traditional Catholic teaching on birth control in the 1968

papal encyclical Humanae Vitae. The encyclical, which reiterated the traditional Catholic teaching that artificial contraception distorted the nature and purpose of sex, was greeted with open dissent by many Catholics, which contributed to the rise of a culture of dissent in following years on other Catholic teachings.[35]

A backlash against oral contraceptives occurred in the early and mid-1970s, when reports and speculations appeared that linked the use of the Pill to breast cancer. Until then, many women in the feminist movement had hailed the Pill as an "equalizer" that had given them the same sexual freedom as men had traditionally enjoyed. This new development, however, caused many of them to denounce oral contraceptives as a male invention designed to facilitate male sexual freedom with women at the cost of health risk to women.[36] At the same time, society was beginning to take note of the impact of the Pill on traditional gender roles. Women now did not have to choose between a relationship and a career; singer Loretta Lynn commented on this in 1975 with a song entitled "The Pill," which told the story of a married woman's use of the drug to liberate herself from her traditional role as wife and mother.

Environmental impact

Ethinylestradiol, the synthetic estrogen used in combined hormonal contraceptives, is excreted in the urine of women users. Sewage treatment processes do not remove these chemicals, and they are discharged into the water system. This form of pollution has been proven to have reproductive and other effects on aquatic organisms, including fish, frogs, and zooplankton. Feminization of male fish, even to the point of producing eggs, is one common effect. Both male and female fish experience delays in reproductive development, and changes are seen in their kidneys and livers.[37]
